Pyrazinamide (PZA) contributes to the killing of *M. tuberculosis*, particularly at a low pH such as that within macrophages. The exact mechanism of action of PZA is controversial. PZA has no effect on extracellular tubercle bacilli in vitro, but contributes to the killing of intracellular bacilli. Primary resistance is very rare except that *Mycobacterium bovis* is intrinsically resistant. The drug diffuses readily into all areas, including the cerebrospinal fluid. The usual pediatric daily dose is 30 to 40 mg/kg (maximum daily dose 2 g) or 50 mg/kg intermittently. The optimal dose for infants and children has not been established firmly; however, young children (<5 years old) have lower serum concentrations of PZA than older children given the same per-kilogram dose [196]. The adult dose is tolerated well by infants and children, results in high cerebrospinal fluid concentrations, and is effective in therapy trials for active tuberculosis in children. PZA seems to exert its maximum effect during the first 2 months of therapy. Hepatotoxicity can occur at high doses, but is rare at the usual dose. PZA routinely causes an increase in the serum uric acid concentration by inhibiting its excretion through the kidneys. Toxic reactions in adults include flushing, cutaneous hypersensitivity, arthralgia, and overt gout; however, the considerable experience with this drug in children in Latin American countries, Hong Kong, and the United States has revealed few problems.

Ethambutol (EMB) has been used for many years as a companion drug for INH in adults. The usual pediatric oral dose is 20 mg/kg/day or 50 mg/kg intermittently (maximum dose 2.5 g). At this dose, the drug primarily is bacteriostatic, its major role being to prevent emergence of resistance to other drugs. At doses greater than 30 mg/kg/day or 50 mg/kg given intermittently, EMB has some

bactericidal action. At these higher doses, optic neuritis or red-green color blindness has occurred in some adults. The incidence of ophthalmologic toxicity in children is extremely low; this may be due in part to children having lower serum levels of EMB than adults who receive the same dose per kilogram [196,197]. EMB is safe in children at recommended doses and is recommended for children of all ages by the WHO [198]. EMB is used frequently and safely in children with life-threatening forms of tuberculosis or with drug-resistant tuberculosis.

Streptomycin (STM) is a valuable drug used in conjunction with INH and RIF in life-threatening forms of tuberculosis. It is bactericidal and tolerated well by children in the usual dose of 20 to 40 mg/kg/day intramuscularly up to 1 g. Usually, STM can be discontinued within 1 to 3 months if clinical improvement is definite, whereas the other two or three drugs are continued with oral administration. Other aminoglycosides, such as amikacin, have broader therapeutic windows and do not show cross-resistance in STM-resistant strains of *M. tuberculosis*.

## GENERAL PRINCIPLES

The tubercle bacillus can be killed only during replication, which occurs among organisms that are active metabolically. In one model, bacilli in a host exist in different populations [7]. They are active metabolically and replicate freely where oxygen tension is high and the pH is neutral or alkaline. Environmental conditions for growth are best within cavities, leading to a large bacterial population. Older children with pulmonary tuberculosis and patients of all ages with only extrapulmonary tuberculosis are infected with a much smaller number of tubercle bacilli because the cavitary population is not present. Neonates with congenital tuberculosis tend to have a large burden of organisms at diagnosis, however.

Naturally occurring drug-resistant mutant organisms occur within large populations of tubercle bacilli even before chemotherapy is started. All known genetic loci for drug resistance in *M. tuberculosis* are located on the chromosome; no plasmid-mediated resistance is known. The rate of resistance within populations of organisms is related to the rate of mutations at these loci. Although a large population of bacilli as a whole may be considered drug-susceptible, a subpopulation of drug-resistant organisms occurs at a fairly predictable rate. The mean frequency of these drug-resistant mutations is about $10^{-6}$, but varies among drugs: STM, $10^{-5}$; INH, $10^{-6}$; and RIF, $10^{-7}$ [199]. A cavity containing $10^9$ tubercle bacilli has thousands of single drug-resistant mutant organisms, whereas a closed caseous lesion contains few, if any, resistant mutants.

The population size of tubercle bacilli within a patient determines the appropriate therapy. For patients with a large bacterial population (adults with cavities or extensive infiltrates), many single drug-resistant mutants are present, and at least two antituberculosis drugs must be used. Conversely, for patients with *M. tuberculosis* infection but no disease, the bacterial population is very small (about $10^3$ to $10^4$ organisms), drug-resistant mutants are rare, and a single drug can be used. Older children with pulmonary tuberculosis and patients of all ages with extrapulmonary tuberculosis have medium-sized populations in which drug-resistant mutants may or may not be present. Generally, these patients should be treated with at least two drugs. Neonates and infants with tuberculosis disease have large mycobacterial populations, and several drugs are required to effect a cure.

## PREGNANT WOMEN

The only drug with well-documented efficacy against *M. tuberculosis* infection in pregnant women is INH. Infants and children tolerate INH very well, and adverse reactions are rare. Adverse reactions are more common in adults. Of young adults taking INH, 7% to 20% have an asymptomatic increase in serum liver transaminase levels; 1% to 2% have symptomatic hepatitis, which is reversible if the medication is stopped immediately [200]. For most young adults, monitoring for hepatitis is done clinically. Routine or periodic evaluation of serum liver enzyme tests is reserved for adults with underlying liver disease or adults taking other potentially hepatotoxic drugs.

Many experts recommend obtaining baseline aspartate aminotransferase, bilirubin, alkaline phosphatase, creatinine, and platelet count [201], and some experts think all pregnant women taking INH should have routine biochemical monitoring for hepatitis. Serum liver enzyme elevations of three to four times normal are common and do not necessitate discontinuation of the drug. There is no evidence that giving INH to a pregnant woman adversely affects the liver of the fetus. The other important adverse reaction of INH is peripheral neuritis caused by inhibition of pyridoxine metabolism. Pyridoxine (25 to 50 mg daily) should be given to pregnant women and breast-feeding infants because breast milk has low concentrations of pyridoxine, even if the mother is receiving vitamin supplements [202].

The current recommendation of the CDC is to treat adults and children infected with *M. tuberculosis* with INH for 9 months [201]. The medication usually is taken daily under self-supervision. If poor patient adherence is likely and resources are available, INH can be given twice weekly using directly observed therapy [203]. Directly observed therapy requires that a health care worker, often from the local health department, observe the patient take antituberculosis medications. Generally, directly observed therapy should be used for all patients with tuberculosis disease because of the difficulty in predicting patient adherence and the consequences of poor adherence (relapse and development of drug resistance). Directly observed therapy is often used for high-risk newborns with tuberculosis exposure or infants with *M. tuberculosis* infection.

For adult patients who cannot take INH for treatment of *M. tuberculosis* infection because of side effects of the medication or because they are infected with an INH-resistant but RIF-susceptible strain of *M. tuberculosis*, the treatment of choice for *M. tuberculosis* infection is RIF for 4 months, which also can be given daily or twice a week under directly observed therapy [204]. If the mother is known to be infected with a strain of tuberculosis that is resistant to INH and RIF (MDR tuberculosis), an expert

should be consulted for the management of the mother and the child after delivery [205].

Although treatment of active tuberculosis during pregnancy is unquestioned, the treatment of a pregnant woman who has asymptomatic *M. tuberculosis* infection is more controversial. Some clinicians prefer to delay therapy until after delivery because pregnancy does not seem to increase the risk of developing active tuberculosis. Others believe that because recent infection can be accompanied by hematogenous spread to the placenta, it is preferable to treat without delay or to wait until the second trimester to start chemotherapy. Some reports suggest that the risk of INH-associated hepatitis and death is higher in women than in men [206] and that women in the postpartum period are slightly more vulnerable to INH hepatotoxicity [207]. These authors suggest that it might be prudent to avoid INH during the postpartum period or at least to monitor postpartum women taking INH within 3 months of delivery with frequent examinations and laboratory studies [200]. The possible increased risk of INH hepatotoxicity must be weighed against the risk of developing active tuberculosis and the consequences to the mother and the infant if active tuberculosis develops.

The indications for treatment and the basic principles of management for the pregnant woman with tuberculosis disease are no different from those in nonpregnant patients. The recommendations for which drugs to use and how long to give them are slightly different, however, mostly because of possible effects of several of the drugs on the developing fetus.

The currently recommended treatment for drug-susceptible pulmonary tuberculosis in the United States in nonpregnant individuals is 6 months of INH and RIF, supplemented during the first 2 months with PZA and EMB [201,208]. With any of the regimens, the drugs usually are given every day for the first 2 weeks to 2 months; then they can be given daily or intermittently (under directly observed therapy) for the remainder of therapy with equal effectiveness and rates of adverse reactions [209].

Untreated tuberculosis represents a far greater risk to a woman and her fetus than appropriate treatment of the disease [91,210–214]. Extensive experience with the use of INH in pregnancy has been reported. Although it crosses the placenta, it is not teratogenic even when given during the first 4 months of gestation [215]. EMB also seems to be safe during pregnancy. In 650 cases in which pregnant women were treated with EMB, no evidence of fetal malformations, including eye abnormalities, was found [112,216–218].

The action of RIF to inhibit DNA-dependent RNA polymerase combined with its ability to cross the placental barrier has created some concern about its use in pregnancy [219]. Only 3% of 446 fetuses exposed in utero to RIF had abnormalities, however, compared with 2% for EMB and 1% for INH [112]. The noted abnormalities included limb reductions, central nervous system abnormalities, and hypoprothrombinemia. Hemorrhagic disease of the newborn also has been described after the use of RIF in the mother. The incidence of abnormalities in fetuses not exposed to antituberculosis medications ranges from 1% to 6%. Generally, the powerful antituberculosis effect of RIF outweighs concern about its effect on the fetus. Nonpregnant women receiving RIF should receive contraception counseling because receiving RIF can impair the efficacy of oral contraceptives, leading to unintended pregnancy in a tuberculous woman [220].

Several antituberculosis drugs generally are not used in pregnant women because of possible toxicity to the fetus [221–223]. STM has variable passage across the placental barrier. Its use in pregnancy is now limited by the availability of better drugs and its effect on the fetus [224–226]. In a review of 206 infants exposed in utero to STM, 34 (17%) had significant eighth cranial nerve damage; abnormalities ranged from mild vestibular damage to profound bilateral deafness [112]. The deleterious effects of STM are independent of the critical periods earlier in embryogenesis, and it is potentially hazardous throughout gestation. It is assumed that capreomycin, kanamycin, and amikacin, other aminoglycosides with antituberculosis activity, could have the same toxic potential as STM. One review of intravenous gentamicin and oral neomycin did not show teratogenicity, however, in a population-based cohort of pregnant women in Hungary [227].

Little is known about the specific effects of PZA on the fetus. Current ATS guidelines recommend avoiding PZA during pregnancy; this strategy would increase length of therapy to 9 months [201]. Although there are no data, an increasing number of experts are using PZA during pregnancy with no reported adverse reactions, and WHO guidelines do not recommend PZA avoidance in pregnancy [228]. Nonspecific teratogenic effects have been attributed to ethionamide [229]. The central nervous system effects of cycloserine and the gastrointestinal effects of para-aminosalicylic acid in adults make their use in pregnancy undesirable.

Fluoroquinolone use is not currently recommended by the ATS during pregnancy because there is concern for arthropathy, and one Danish study showed a higher rate of bone malformations in the offspring of women who received fluoroquinolones in the first trimester [230]. For adults with MDR tuberculosis, fluoroquinolones may be essential components of the therapeutic regimen, however, and risk-benefit analysis must be considered carefully. Fluoroquinolone use is not recommended for breast-feeding mothers [201]; however, there have been no reports of arthropathy in children under these conditions. Numerous second-line agents (e.g., aminoglycosides, cycloserine, ethionamide, fluoroquinolones, para-aminosalicylic acid) have been used successfully to treat pregnant women with MDR tuberculosis, and short follow-up analyses have shown no evidence of teratogenicity in the children of these patients [231,232].

The currently recommended initial treatment of drug-susceptible tuberculosis disease in pregnancy is INH and RIF daily, with the addition of EMB initially, under directly observed therapy [233,234]. Pyridoxine (50 mg daily) always should be given with INH during pregnancy because of the increased requirements for this vitamin in pregnant women. After drug susceptibility testing of the isolate of *M. tuberculosis* reveals it to be susceptible to INH and RIF, EMB can be discontinued. If PZA is not

used in the initial regimen, INH and RIF must be given for 9 months instead of 6 months. After the first 2 weeks to 2 months of daily treatment, the drugs can be given twice a week under directly observed therapy, which is the preferred method of treatment by most experts. The treatment of any form of drug-resistant tuberculosis during pregnancy is extraordinarily difficult and should be handled by an expert with great experience with the disease [235].

Because treatment of tuberculosis in pregnant women often continues after delivery, there is concern as to whether it is safe for the mother to breast-feed her infant. Snider and Powell [236] concluded that a breast-feeding infant would have serum levels of no more than 20% of the usual therapeutic levels of INH for infants and less than 11% of other antituberculosis drugs. Potential toxic effects of drugs delivered in breast milk have not been reported. Because pyridoxine deficiency in neonates can cause seizures, and because breast milk has relatively low levels of pyridoxine, infants who are taking INH or whose breast-feeding mothers are taking INH should receive supplemental pyridoxine [237].

Pregnant women coinfected with HIV and tuberculosis present multiple treatment challenges because each disease potentiates the other, and there are often interactions between RIF and antiretroviral therapy [238]. Additionally, patients who are coinfected are at risk for paradoxical disease worsening after starting antimycobacterial therapy—immune reconstitution inflammatory syndrome (IRIS)—which occasionally can be fatal [239]. Maternal mortality rates are higher for coinfected women than for women with either infection alone, and much of the excess mortality is due to tuberculosis [96,238].

## NEONATES AND INFANTS

The optimal treatment of congenital tuberculosis has not been established because the rarity of this condition precludes formal treatment trials. The basic principles for treatment of other children and adults seem also to apply to the treatment of congenital tuberculosis [193,240]. All children with suspected congenital tuberculosis should be started on four antituberculosis medications (INH, RIF, PZA, plus either EMB or an aminoglycoside) until the diagnostic evaluation and susceptibility testing of isolated organisms are concluded. Although the optimal duration of therapy has not been established, many experts treat infants with congenital or postnatally acquired tuberculosis for 9 to 12 months because of the decreased immunologic capability of the young infant.

INH given alone is known to be safe in neonates, including premature infants. There are no comparable data for INH given in combination with other drugs or for other drugs alone. Several studies have shown that RIF can be given safely to premature infants for indications other than tuberculosis. In addition, anecdotal information supports the notion that PZA, STM, amikacin, and kanamycin are safe in neonates. Young infants taking these drugs should have biochemical monitoring of serum liver enzymes and uric acid (for PZA) performed on a regular basis. Hearing screens and evaluation of renal function should be considered for children taking aminoglycosides. Although the pharmacokinetics of antituberculosis drugs in neonates are essentially unknown, extensive clinical experience suggests that the doses listed in Table 18–3 are effective and safe. All neonates and infants with tuberculosis should be treated by directly observed therapy.

## FOLLOWING THE INFANT ON THERAPY

Follow-up of children treated with antituberculosis drugs has become more streamlined in recent years. While receiving chemotherapy, patients should be seen monthly to encourage regular taking of the prescribed drugs and to check, by a few simple questions (e.g., concerning appetite, well-being) and a few observations (e.g., weight gain; appearance of skin and sclerae; palpation of liver, spleen, and lymph nodes), that the disease is not spreading and that toxic effects of the drugs are not appearing. Repeat chest radiographs probably should be obtained 1 to 2 months after the onset of chemotherapy to ascertain the maximal extent of disease before chemotherapy takes effect; thereafter, radiographs rarely are necessary.

Chemotherapy has been so successful that follow-up beyond its termination is not usually necessary except for children with serious disease, such as congenital tuberculosis or meningitis, or children with extensive residual chest radiographic findings at the end of chemotherapy. By law, every case of definite or suspected tuberculosis must be reported immediately by telephone to the health department to ensure (1) prompt contact investigation [241–247]; (2) free antituberculosis drugs, which are available for diagnosed cases and for intimate contacts in almost every state of the United States; and (3) provision of directly observed therapy.

## PROGNOSIS

The prognosis for congenital tuberculosis was dismal in the prechemotherapy era [248]. In Hughesdon's report [135], 3 infants died on the first day of life, 8 died between 18 and 30 days, 15 died between 31 and 60 days, and 3 died between 65 and 112 days. Hageman and associates [129] reviewed 26 patients born since the introduction of INH in 1952: 12 died, and 9 of these were untreated, the diagnosis being established only at autopsy. The results in survivors were good, but the follow-up was usually short [182,249]. A child reported by Nemir and O'Hare [130], who was treated intensively with INH, STM, and aminosalicylic acid in the 1950s, recovered, was followed for 27 years, and is herself the mother of two tuberculin-negative children.

In the modern era, mortality rates of 38% have been reported in some series [238]. All-cause mortality rates are 3.4-fold higher in children born to mothers with tuberculosis [96]. Children of mothers coinfected with untreated HIV and tuberculosis have a high rate of HIV acquisition [96], and in one series, almost two thirds of children died before 1 year of age [97]. There is little question that today's multidrug, short-course chemotherapeutic regimens should be extremely effective in bringing the disease under rapid and permanent control,

if the disease is due to drug-susceptible organisms. Experience with treatment of tuberculosis disease that is due to drug-resistant organisms is so limited as to preclude prognosis.

## VACCINATION AGAINST TUBERCULOSIS—BACILLE CALMETTE-GUÉRIN

The BCG vaccines are the oldest of the vaccines used throughout the world. They have been given to 4 billion people and have been used routinely since the 1960s in every country of the world except the United States and the Netherlands [250]. Despite their widespread use, tuberculosis remains among the most destructive infectious diseases in the world, however, indicating that the BCG vaccines alone are not sufficient to eliminate or even control the disease. The vaccine is generally administered during the newborn period. In some countries, children receive a booster of BCG during adolescence [251,252].

### HISTORY AND DEVELOPMENT OF BACILLE CALMETTE-GUÉRIN VACCINES

The BCG vaccines are attenuated strains of *M. bovis*. Starting in 1908, the original strain was subcultured every 3 weeks for 13 years [253]. The genotype changes that resulted at various stages cannot be determined because none of the original cultures or subcultures were preserved. This long process was marked by a loss of virulence first for calves, then for guinea pigs. In 1948, despite the complete lack of reported controlled trials or case-control studies, the First International BCG Congress stated that the BCG vaccines were effective and safe. After World War II, the WHO and UNICEF organized campaigns to promote vaccination with BCG in several countries. The seed lot system for BCG was established in 1956 [253], and the WHO developed requirements for freeze-dried BCG in 1966 [254]. By the end of 1974, more than 1.5 billion individuals had received a BCG vaccination. Since 1977, BCG vaccination has been included in the WHO Expanded Programme on Immunization. Approximately 100 million children receive a BCG vaccination each year, expanding the total number of individuals who have received it to more than 4 billion.

The original strain of *M. bovis* used to make BCG was maintained by serial passage at the Pasteur Institute until it was lost or discarded. It previously was distributed to dozens of laboratories, each of which produced and maintained its own BCG stain. It soon became apparent that the conditions for culture used in the various laboratories resulted in the production of many "daughter" BCG strains that differed widely in growth characteristics, biochemical activity, ability to induce delayed hypersensitivity, and animal virulence [255–258]. The patterns of large restriction fragments created by the digestion of BCG DNA vary among strains [259]. In the 1960s, the WHO recommended stabilization of the biologic characteristics of the derivative strains by lyophilization and storage at low temperatures [260].

Interlaboratory studies and genomic evaluation have shown that the BCG strains in use today vary widely in many characteristics [261,262]. Different strains of BCG can activate different immune pathways and incite varying proinflammatory cascades [263]. The possible consequences on vaccine efficacy and adverse effects are unknown, however. When comparing the various published clinical trials and case-control series, it is difficult to show that one strain of BCG is superior to another in the protection of humans against tuberculosis. Some laboratory and clinical observations have suggested that BCG strains can be separated into "strong" (Pasteur 1173 P2, Danish 1331) and "weak" (Glaxo 1077, Tokyo 172) groups. Although the relative efficacy of these two groups has been inconsistent, the strong strains have been associated with a higher rate of adverse reactions in neonates, including lymphadenitis and osteitis [264–267]. One South African study showed that after a change from the Tokyo 172 BCG to the Danish 1331 BCG, the rates of disseminated tuberculosis disease declined [268].

There is no consensus about which strain of BCG is optimal for general use. It has been postulated that investigators and public health authorities have selected BCG strains by their desire to maximize tuberculin reactivity and minimize adenitis, which may create strains that are the inverse of the ideal vaccine. It also seems that some BCG strains have lost efficacy over time [269].

### VACCINE PREPARATION AND ADMINISTRATION

Seed lots are lyophilized bacilli that are part of the original harvest of the various BCG strains. The bacilli usually are grown in Sauton medium and are harvested early (day 6 to 9) to ensure good survival of organisms after lyophilization. The mass of mycobacterial cells is filtered, pressed, homogenized, diluted, and then freeze-dried. Reconstituted vaccines contain live bacilli and dead bacteria. Regulating the ratio of live to dead organisms is an important aspect of quality control and can affect efficacy and rates of adverse reactions.

Most BCG vaccine programs use the intradermal route of administration employing a syringe and needle; the dose is 0.05 mL for children in the first year of life and 0.1 mL for children older than 12 months of age. Japan and most of South Africa use percutaneous administration with a multipuncture device. It is generally accepted that the intradermal method is more accurate and consistent because the dose is measured precisely, and the administration is controlled. The deltoid region of the arm is the most common injection site, although many other body sites are used in individual patients.

Greater than 90% of patients receiving their first BCG vaccination develop a local reaction (e.g., erythema, induration, tenderness) followed by healing and scar formation within 3 months. One West African study showed that BCG-vaccinated children who had a BCG scar had significantly lower all-cause mortality rates than vaccinated children who did not develop a scar [270]. Possible explanations are that the development of a BCG scar is a marker of cell-mediated immunity, that infants who are premature or of low birth weight are less likely to develop scars [271], that the BCG vaccine may have nonspecific activity against unrelated bacterial pathogens,

or that vaccine failure may play a role in the failure to develop a scar.

Other methods of administration were developed to try to address problems of local reactions created by intradermal administration. Subcutaneous injection seems to be effective, but often produces retracted scars. Other techniques, such as scarification, jet injection, and use of bifurcated needles, have yielded highly variable and, in some cases, inadequate results [272]. There have been no conclusive reported trials that compared the various techniques of BCG administration for protection against tuberculosis, but local complication rates generally are lowest with the multipuncture devices.

## ADVERSE REACTIONS TO BACILLE CALMETTE-GUÉRIN VACCINATION

Local ulceration and regional lymphadenitis are the most common complications, occurring in less than 1% of immunocompetent recipients after intradermal administration of BCG [273,274]. These lesions usually occur within a few weeks to months after vaccination, but can be delayed for months in immunocompetent persons and for years in immunocompromised hosts [275]. Axillary, cervical, or supraclavicular nodes may be involved on the ipsilateral side of vaccination. Outbreaks of lymphadenitis after BCG vaccination have followed the introduction of a new BCG strain into the vaccination program [276,277]. There is no evidence that children who experience local complications are more likely to have immune deficits or to have enhanced or diminished protection against tuberculosis [276,277]. Because the risk of lymphadenitis is significantly higher when newborns are given a full dose of BCG, the WHO recommends using a reduced dose in children younger than 30 days of age.

The treatment of local adenitis as a complication of BCG vaccination is controversial, with suggestions ranging from observation to surgical drainage to administration of antituberculosis chemotherapy to a combination of surgery and chemotherapy [278]. Nonsuppurative lymph nodes usually resolve spontaneously, although resolution may take several months [279,280]. The WHO recommends drainage and direct installation of an antituberculosis drug into the lesion for adherent or fistulated lymph nodes [281]. One study of 120 patients with BCG-induced lymphadenitis treated for 6 months with an oral antituberculosis drug showed, however, that medical therapy was no better than observation, and that the rate of spontaneous drainage of lymph nodes was higher among children who received INH than children who were observed only [282]. Most experts now agree that nonsuppurative adenitis associated with BCG vaccination should be managed by observation only.

Other complications of BCG vaccination are far less frequent. The mean risk of osteitis after BCG vaccination has varied from 0.01 per 1 million in Japan to 300 per 1 million in Finland [283–285]. As with lymphadenitis, osteitis rates occasionally have increased dramatically after introduction of a new vaccine strain into a vaccination program. Other very rare complications of BCG vaccination include lupus vulgaris, erythema nodosum, iritis, and osteomyelitis. Generally, these complications should be treated with antituberculosis medications (except PZA, to which *M. bovis* is intrinsically resistant).

Generalized BCG infection is extremely rare in immunocompetent hosts [286–288]. Overall rates of fatal disseminated BCG disease in recently vaccinated persons have been reported at 0.19 to 1.56 cases per 1 million vaccinated, most cases occurring in children with severe defects in cellular immunity, such as severe combined immunodeficiency, malnutrition, cancer, DiGeorge syndrome, interferon-$\gamma$ receptor deficiency, or symptomatic HIV infection [273,289–295]. It is likely that the actual incidence of disseminated BCG infection is higher because some cases undoubtedly are misdiagnosed as disseminated tuberculosis.

The exact safety of BCG vaccination in children and adults with HIV infection is unknown. Disseminated BCG infection was described in an HIV-infected adult 30 years after he received BCG [296]. BCG can also be associated with immune reconstitution syndrome in children, generally within 10 weeks of initiating antiretroviral therapy [297]. One French study showed that 9 of 68 HIV-infected children given BCG vaccine developed complications: 7 had large satellite adenitis, and 2 developed disseminated lesions [298]. A retrospective review of BCG disease cases in the Western Cape Province of South Africa found 25 cases in a 2.5-year period, or 1 in every 240 HIV-infected vaccinees. Seventeen (68%) patients were HIV-infected; immunocompetent children were more likely to have regional disease at the inoculation site, whereas immunocompromised hosts were at risk for disseminated disease [299].

Because many HIV-infected children were asymptomatic before presentation, and disease was severe in nature, new WHO guidelines (2007) modified recommendations for BCG vaccination in HIV-infected children. Prior WHO guidelines recommended giving BCG vaccination to asymptomatic HIV-infected infants who live in high-risk areas for tuberculosis. Current guidelines recommend avoiding BCG vaccination in two groups: (1) children known to be HIV-infected, regardless of symptomatic categorization, and (2) children of uncertain HIV infection status with signs or symptoms of HIV infection born to HIV-infected mothers [300]. Asymptomatic children of uncertain HIV infection status born to HIV-infected mothers should receive the BCG vaccine if the perceived benefits outweigh the risk of disseminated BCG infection. Despite the presence of live BCG organisms in ulcerated vaccination sites, person-to-person transmission of BCG has never been documented.

## EFFECT OF BACILLE CALMETTE-GUÉRIN VACCINATION ON TUBERCULIN SKIN TEST RESULTS

Although the BCG vaccines have an effect on the result of the tuberculin skin test, the effect is variable, and no reliable method can distinguish tuberculin reactions caused by BCG vaccination from reactions caused by infection with *M. tuberculosis*. In various studies with different populations, the proportion of previously BCG-vaccinated individuals with significant skin test reactions has ranged from 0% to 90% [301–305]. The size of the skin test

reaction after BCG vaccination varies with the strain and dose of the vaccine [303,306], the route of administration [305,307], the age at vaccination [271,302,308], the child's nutritional status, the time interval since vaccination [251,302,308], and the frequency of skin testing [309].

Several studies have shown that when newborns are given a BCG vaccination, 50% may have a negative tuberculin skin test reaction at 6 months of age, and most have a negative reaction by 2 to 5 years of age [302,310,311]. Interpretation of the skin test in BCG-vaccinated children may be complicated, however, by the booster phenomenon. The booster effect is the increase in reaction size caused by repetitive testing in a person sensitized to mycobacterial antigens [312]. Skin test reactions can be boosted in children who previously received a BCG vaccination, giving the false impression of "conversion" of a skin test from negative to positive, which usually indicates a new tuberculosis infection [313].

Strong or severe reactions to a tuberculin skin test are rare in previously BCG-vaccinated individuals who are *not* also infected with *M. tuberculosis*. Prior receipt of a BCG vaccine is never a contraindication for tuberculin skin testing. Most skin reactions caused by BCG vaccination are less than 10 mm in size. Generally, the tuberculin skin test should be interpreted in the same manner for an adult or child who has received a BCG vaccination as it is for a person with similar epidemiologic characteristics who has not received BCG vaccination.

## EFFECTIVENESS OF BACILLE CALMETTE-GUÉRIN VACCINES

A detailed discussion of the effectiveness of the BCG vaccines and the variables which may have an impact on effectiveness is beyond the scope of this chapter. There have been eight major controlled trials conducted in various populations and many published case-control and cohort studies of various BCG preparations [314,315]. Investigators at the Harvard School of Health found 15 prospective trials and 12 case-control studies that met their criteria for adequacy in study design and controls against potential bias. In the prospective trials, the protective effect of BCG vaccines against tuberculosis disease was 51% [315]. Analysis of eight studies involving only vaccination of newborns revealed a protective effect of 55% [314]. For trials that measured these outcomes, BCG vaccines showed 71% protection against death from tuberculosis, 64% protection against tuberculosis meningitis, and 72% protection against disseminated tuberculosis. Another meta-analysis estimated that the approximately 100 million BCG vaccinations administered in 2002 would prevent almost 30,000 cases of meningitis and more than 11,000 cases of miliary tuberculosis, with highest numbers of cases prevented in Southeast Asia and sub-Saharan Africa [316].

Different BCG preparations and strains used in the same population gave similar levels of protection, whereas genetically identical BCG strains gave different levels of protection in different populations [314,315]. The duration of any protective effect is poorly studied and unknown, but probably short-lived (<10 years at best). There are no data on the efficacy of BCG vaccines in HIV-infected children, and given the risk of disseminated BCG disease and severe local reactions, HIV seropositivity is a contraindication to receipt of the BCG vaccine [300].

It seems that BCG vaccines have worked well in some circumstances, but poorly in others. Because only a small percentage of infectious cases of tuberculosis in adults are prevented by childhood BCG vaccination, BCG vaccination as currently practiced is not an effective instrument of disease control. The best use of BCG is the prevention of life-threatening forms of tuberculosis—meningitis, disseminated, severe pulmonary disease—in infants and young children.

## MANAGEMENT OF A NEONATE BORN TO A MOTHER WITH A POSITIVE TUBERCULIN SKIN TEST

If a mother with a positive tuberculin skin test is well and her chest radiograph result is normal, no separation of the mother and infant is required. Although the mother is a candidate for treatment of *M. tuberculosis* infection, the infant does not need special evaluation or therapy. Other family members should have a tuberculin skin test and further evaluation, if indicated. The local health department often does not have the resources to do this testing, however, which should be performed by the treating physicians. There is no need to delay discharge of the infant from the newborn nursery pending the results of this family investigation. The need for further evaluation of the infant depends on whether disease is found in the family or cannot be excluded within the family's environment.

If the radiograph is abnormal, the mother and infant should be separated until the mother has been evaluated thoroughly. If active tuberculosis is present in the mother, she should be started on effective antituberculosis medications right away. Examination of the mother's sputum for acid-fast organisms always is necessary even if obtaining a sample requires vigorous measures. All other household members and frequent visitors should be investigated for *M. tuberculosis* infection and disease.

If the mother's chest radiograph is abnormal, but the history, physical examination, sputum smear, and interpretation of the radiograph suggest no evidence of active tuberculosis, it is reasonable to assume that the infant is at low risk for infection. The radiographic abnormality is due to another cause or a quiescent focus of previous infection with *M. tuberculosis*. If the mother remains untreated, however, she may develop reactivation tuberculosis and subsequently expose her infant. If not previously treated, the mother should receive appropriate therapy, and she and her infant should receive frequent follow-up care. In this situation, the infant does not need chemotherapy. All household members should be evaluated for tuberculosis by a clinician.

If the mother has clinical and radiographic evidence of active, possibly contagious tuberculosis, the local health department should be informed immediately about the mother so that a contact investigation can be performed. The infant should be evaluated for congenital tuberculosis with a physical examination and high-quality

posteroanterior and lateral chest radiographs. If possible, serologic testing for HIV should be performed on the mother and her infant. The mother and infant should be separated until the infant is receiving chemotherapy or the mother is judged to be noncontagious [317]. Prophylactic INH (10–15 mg/kg/day) for newborns born to mothers with tuberculosis has been so efficacious that separation of the mother and infant is no longer considered mandatory when therapy is started [318–320]. Separation should occur only if the mother is ill enough to require hospitalization, if she has been or is expected to become nonadherent to her treatment, or if she is thought to be infected with a drug-resistant strain of *M. tuberculosis*.

INH therapy should be continued in the infant at least until the mother has been shown to be culture-negative for 3 months. At that time, a Mantoux tuberculin skin test is done on the infant. If it is positive, the infant should be investigated for the presence of tuberculosis with a physical examination and chest radiograph and further appropriate work-up if disease is suggested. If disease is absent, the infant should continue INH for 9 months. If the follow-up skin test is negative, and the mother or contact with tuberculosis has good adherence and response to treatment, INH many be discontinued in the infant. The infant needs close follow-up, and it is prudent to repeat a tuberculin skin test after 6 to 12 months.

If the mother or other family member with contagious tuberculosis has disease caused by an MDR strain of *M. tuberculosis* or has poor adherence to treatment, and better supervision of therapy for the adult and infant is impossible, the CDC recommends that the infant be separated from the contagious adult. Vaccination with BCG may be considered, as long as the infant is not HIV-infected [300,321,322]. Vaccination with BCG seems to decrease the risk of tuberculosis in exposed infants, but the effect is variable [323,324].

Kendig [325] reported 117 infants born to mothers with active tuberculosis around the time of delivery; none of the 30 BCG-vaccinated infants developed tuberculosis, and 38 cases of tuberculosis and 3 deaths occurred among the 75 infants who received neither BCG vaccine nor INH therapy. Twenty-four of the 30 infants who received BCG vaccine also were separated from their mother for at least 6 weeks; it is impossible to determine what degree of protection was conferred by this separation. Similar studies in England and Canada also describe the apparent efficacy of BCG given to neonates [326]. Usually, the infant must be kept out of the household, away from the contagious case, until the skin test result becomes reactive (marking protection from infection). Some infants who receive a BCG vaccination do not develop a reactive tuberculin skin test, however.

It is unknown if developing a reactive skin test correlates with protection. It is also unknown if a second BCG vaccination given to a child who maintains a negative tuberculin skin test reaction after the first BCG vaccination would cause an enhanced level of protection. Although BCG vaccines have some protective effect for the exposed newborn, most experts in the United States believe that appropriate separation and taking whatever steps are necessary to provide adequate chemotherapy for the child and the contagious adult is a superior approach to BCG vaccination. The use of directly observed therapy has made the need for BCG vaccination of infants in the United States almost nonexistent.

## MANAGEMENT OF NEONATES AFTER POSTNATAL EXPOSURE

Occasionally, workers in nurseries have been found to have infectious tuberculosis [143,327–329]. These experiments of nature provide useful data on the risk to the infants. Generally, risk of infection of neonates in a modern hospital nursery seems to be low. Most nurseries have large air volumes, flows, and adequate air exchanges to decrease risk of infection. Also, the minute volume of neonates is low, diminishing the risk of infection after a brief time of exposure. Light and coworkers [319] followed 437 infants exposed to a nurse with a cough and a sputum smear that was positive for tuberculosis. Of these infants, 160 were considered to be at greatest risk and received daily INH for 3 months; all infants remained tuberculin-negative. Nania and colleagues [328] investigated exposures in a neonatal intensive care unit after a respiratory therapist was diagnosed with acid-fast bacilli smear-positive tuberculosis. Over a 1-month period, 180 infants were potentially exposed, as were 240 coworkers. No cases of tuberculosis infection or disease were identified. Steiner and colleagues [143] observed development of miliary tuberculosis in 2 of 1647 infants exposed in a nursery.

Infection is rare under nursery conditions, but it can and does occur. Strict control measures should prevent such episodes. Nursery personnel should undergo Mantoux testing or whole-blood interferon-$\gamma$ release assays before starting work and, if the result is negative, yearly thereafter. If the skin test is positive, a prospective employee should have a chest radiograph. If the radiograph is normal, appropriate therapy for *M. tuberculosis* infection should be given, accompanied by careful medical follow-up. Prospective employees with positive skin tests and abnormal chest radiographs must be carefully and thoroughly evaluated. Many require antituberculosis therapy. Theoretically, these same guidelines apply to workers in licensed and unlicensed day care facilities, but in many cases they have not yet been implemented.

The decision to administer chemoprophylaxis to infants exposed in nurseries is controversial. In cases in which the source case is deemed not to be highly contagious through evaluation of the close adult contacts, and where contact between the source case and child was minimal, the infant usually can be managed without antituberculosis chemotherapy. One decision analysis evaluated whether INH prophylaxis was preferable, given the low risk of exposure, risk of INH-induced hepatotoxicity, and risk of severe disease in affected neonates. The model suggested that prophylaxis was preferable, unless the probability of infection was extremely low. The incremental cost-effectiveness was greater than $21 million per death prevented, however [330].

Children with primary tuberculosis are rarely contagious because of the nature of their pulmonary disease, absence of forceful cough, and small number of organisms in the diseased tissue [331,332]. Infants with congenital

tuberculosis often have extensive pulmonary involvement with positive acid-fast stains of tracheal aspirates and numerous tubercle bacilli in the lungs and airways [333,334]. In several cases, there has been evidence of transmission of *M. tuberculosis* from congenitally infected infants to health care workers [335–340]; transmission to other infants has not been reported except in one neonate likely infected because of transmission from contaminated respiratory equipment [341]. Neonates with suspected congenital tuberculosis should be placed in appropriate isolation until it can be determined that they are not infectious, by acid-fast stain and culture of respiratory secretions.

If a member of the household other than the mother is found to have or to have had tuberculosis recently, chemotherapy and BCG vaccine for the infant remain controversial. If the tuberculous family member has completed treatment in the past, that individual should undergo a checkup before the infant enters the home. If the family member is still being treated, he or she should have been sputum culture-negative for at least 3 months before contact with the infant. If the infant must return to a home in which one of the family members has only recently started treatment, he or she should receive daily INH for at least 3 to 4 months, which Dormer and associates [318] showed to be very effective in preventing the development of tuberculosis in infants born to mothers in a sanatorium. If the family cannot be relied on to administer daily medication, if directly observed therapy is impossible, or if there are numerous household members suspected to have tuberculosis, BCG vaccination of the neonate should be considered.

## CONCLUSION

Perinatal tuberculosis, although rare, will continue to occur, particularly among high-risk groups such as blacks, Hispanics, Asian/Pacific Islanders, and Native American/Alaskan natives, and particularly among recent immigrants to the United States. Intrauterine transmission to the fetus occurs particularly in pregnant women experiencing initial *M. tuberculosis* infection and disease such as pleural effusion or miliary tuberculosis; less often, it is a complication of endometrial tuberculosis. Postnatal tuberculosis is usually acquired from a mother, other close family member, or caregiver with cavitary tuberculosis. Only by keeping the possibility of tuberculosis in mind and by carrying out appropriate history taking and tuberculin testing of pregnant patients, particularly pregnant women from high-risk groups, can tuberculosis be diagnosed and treated in time in the mother and newborn. If it does occur and is diagnosed in time, intensive treatment should result in an excellent outcome.

CHAPTER 19

# *CHLAMYDIA* INFECTIONS

**Toni Darville**

## CHAPTER OUTLINE

In 1911, Lindner and colleagues [1] identified typical intracytoplasmic inclusions in infants with a nongonococcal form of ophthalmia neonatorum called *inclusion conjunctivitis of the newborn* (ICN) or inclusion blennorrhea, leading to the elucidation of the epidemiology of sexually transmitted chlamydial infections. Mothers of affected infants were found to have inclusions in their cervical epithelial cells, and fathers of affected infants had inclusions in their urethral cells. For 50 years, cytologic demonstration of chlamydial inclusions in epithelial cells was the only diagnostic procedure available. When chlamydial isolation procedures were developed, first in the yolk sac of the embryonated hen's egg and later in tissue culture, studies again showed *Chlamydia trachomatis* as the etiology of conjunctivitis in the index case and then confirmed the genital tract reservoir of the agent [2]. Although ICN was studied for 60 years, an appreciation of the importance of chlamydial infection of the respiratory tract in infants did not evolve until the late 1970s, with the impetus of the report by Beem and Saxon [3].

*C. trachomatis* is now recognized as the most common sexually transmitted pathogen in Western industrialized society. Although most *C. trachomatis* infections in men and women are asymptomatic, infection can lead to severe reproductive complications in women. The infection can be transmitted from an infected mother to her newborn during delivery, producing conjunctivitis or pneumonia or both. *C. trachomatis* is likely the most common cause of conjunctivitis in infants younger than 1 month of age and is a common cause of afebrile pneumonia in infants younger than 3 months.

DOI: 10.1016/B978-1-4160-6400-8.00019-5

## EPIDEMIOLOGY AND TRANSMISSION

*C. trachomatis* is the most common bacterial cause of sexually transmitted infections in the United States. Reported prevalence rates in the United States include 2% to 7% among female college students, 4% to 12% among women attending a family planning clinic, and 6% to 20% among men and women attending a clinic for sexually transmitted diseases or persons entering correctional facilities [4,5]. In the United Kingdom, data suggest that the rate of infection among young women exceeds 10% [6]. Prevalence rates have declined in areas where screening and treatment programs have been implemented [7]. Many men and most women infected with *C. trachomatis* are either asymptomatic or minimally symptomatic, and presentation for diagnosis is a result of screening or referral after a contact develops symptoms. This is in contrast to gonococcal infections, in which most infected individuals are symptomatic and present acutely for care. Regional estimates are hampered by underdiagnosis and underreporting of cases. Because symptoms are absent or minimal in most women and many men, a large reservoir of asymptomatic infection is present that can sustain the pathogen within a community.

Young age (<20 years) is the sociodemographic factor most strongly associated with chlamydial infection (relative risk among women <25 years old compared with older women is 2 to 3.5) [8]. Although the prevalence of chlamydial infection is increased in black or socioeconomically disadvantaged individuals, there is broad socioeconomic and geographic distribution of infection [9,10]. Other risk factors for cervical chlamydial infection in women are anatomic or hormonal (i.e., use of depot-medroxyprogesterone acetate injections [11] or ectopy after use of oral contraceptives), behavioral (i.e., number of sexual partners), or microbiologic (i.e., concurrent gonorrhea) [12].

For purposes relevant to this chapter, the major method of transmission of *C. trachomatis* is sexual. The child-to-child and intrafamilial infecting patterns that predominate in trachoma endemic areas have not been proven to cause disease in newborns [13]. Chlamydiae cause one-third to one half of nongonococcal urethritis in men, and concomitant infections with gonococci are common in both men and women [14,15].

An infant born to a mother with a chlamydial infection of the cervix is at 60% to 70% risk of acquiring the infection during passage through the birth canal [16]. Of exposed infants, 20% to 50% develop conjunctivitis, and 10% to 20% develop pneumonia. The rectum and vagina of infants exposed during delivery may also be infected, but a clear-cut relationship with disease in these sites has not yet been elucidated [17]. In utero transmission is not known to occur. Infection after cesarean section is seen rarely, usually after premature rupture of the membranes. No evidence supports postnatal transmission from the mother or other family members.

Studies in the 1980s identified *C. trachomatis* in 14% to 46% of infants younger than 1 month of age with conjunctivitis [18]. The prevalence of neonatal chlamydial inclusion conjunctivitis has decreased in recent years in areas where screening and treatment of chlamydial infection in pregnant women is a regular practice [19]. In the Netherlands, prenatal screening for *C. trachomatis* is not routine. Evaluation of infants younger than 3 months of age referred to a Dutch children's hospital or to an ophthalmologist for evaluation of persistent conjunctivitis from 1996-2002 revealed *C. trachomatis* infection in 63% [20].

There is no evidence to suggest that infants with chlamydial infections should be isolated. Transmission of the organism to other infants in nurseries or intensive care units has not been reported. Standard precautions consisting of hand hygiene between patient contacts is recommended. Use of protective gloves, masks or face shields, and nonsterile gowns is recommended when performing procedures likely to generate splashes of body fluids, secretions, or excretions.

## MICROBIOLOGY

### PATHOGEN

Chlamydiae are obligate intracellular parasites that cause various diseases in animal species at virtually all phylogenetic levels. Traditionally, the order Chlamydiales has contained one genus with four recognized species: *C. trachomatis*, *Chlamydia psittaci*, *Chlamydia pneumoniae*, and *Chlamydia pecorum*. More recent taxonomic analysis involving the 16S and 23S rRNA genes have found that the order Chlamydiales contains at least four distinct groups at the family level and provides a potential rationale for splitting the genus *Chlamydia* into two genera, *Chlamydia* and *Chlamydophila* [21]. The genus *Chlamydophila* would contain *C. pneumoniae*, *C. pecorum*, and *C. psittaci*. This new classification continues to be controversial, and for the purposes of this chapter these organisms are referred to as *Chlamydia*.

*C. psittaci* is responsible for psittacosis, a chlamydial infection contracted by humans from infected birds and characterized by interstitial pneumonitis. This infection should be suspected in any patient with atypical pneumonia who has contact with birds. *C. pneumoniae* causes pneumonia, pharyngitis, and bronchitis in humans and may accelerate atherosclerosis. Epidemiologic studies have revealed that *C. pneumoniae* is a common cause of infection in school-age children and young adults; along with *Mycoplasma*, it is probably the most common cause of community-acquired pneumonia in this age group. It is not known to cause disease in newborns and is not discussed further. *C. trachomatis* is associated with a spectrum of diseases. The species *C. trachomatis* contains 18 serologically distinct variants known as serovars. Serovars A, B, Ba, and C cause ocular trachoma, a major cause of blindness in many developing countries, particularly in Africa, Asia, and the Middle East. Ocular trachoma is considered the most common cause of preventable blindness in the world. Three serovars, $L_1$, $L_2$, and $L_3$, are associated with lymphogranuloma venereum, a sexually transmitted disease that is rare in the United States, but is still quite prevalent in many developing countries, and are particularly prevalent in tropical and subtropical areas. Perinatal transmission is rare with lymphogranuloma venereum. Serovars D through K produce infections of the genital tract—urethritis and epididymitis in men and cervicitis and salpingitis in women—the most prevalent chlamydial diseases. Major complications of female genital tract disease include acute pelvic inflammatory disease, ectopic pregnancy, infertility, and infant pneumonia and conjunctivitis.

Similar to gram-negative bacteria, chlamydiae have an outer membrane that contains lipopolysaccharide and membrane proteins, but their outer membrane contains no detectable peptidoglycan, despite the presence of genes encoding proteins for its synthesis [22]. This more recent genomic finding is the basis for the so-called chlamydial peptidoglycan paradox, for it has been known for years that chlamydial development is inhibited by β-lactam antibiotics. Although chlamydiae contain DNA, RNA, and ribosomes, during growth and replication they obtain high-energy phosphate compounds from the host cell. Consequently, they are considered energy parasites. The chlamydial genome size is only 660 kDa, which is smaller than that of any other prokaryote except *Mycoplasma* species. All chlamydiae encode an abundant protein, the major outer membrane protein (MOMP) that is surface exposed in *C. trachomatis* and *C. psittaci*, but not in *C. pneumoniae* [23]. MOMP is the major determinant of the serologic classification of *C. trachomatis* and *C. psittaci* isolates.

## CHLAMYDIAL DEVELOPMENTAL CYCLE

The biphasic developmental cycle of chlamydiae is unique among microorganisms and involves two highly specialized morphologic forms, as shown in Figure 19–1. The extracellular form or elementary body (EB) contains extensive disulfide cross-links within and between outer membrane proteins giving it an almost sporelike structure that is stable outside of the cell. The small (350 nm in diameter) infectious EB is inactive metabolically. The developmental cycle is initiated when an EB attaches to a susceptible epithelial cell. Numerous candidate adhesins have been proposed, but their identity and that of associated epithelial cell receptors remain uncertain. One documented mechanism of entry into the epithelial cell is by receptor-mediated endocytosis via clathrin-coated pits [24], but evidence exists that chlamydiae may exploit multiple mechanisms of entry. The process of EB internalization is very efficient, suggesting that EBs trigger their own internalization by cells that are not considered professional phagocytes.

When inside the cell, surface antigens of the EB seem to prevent fusion of the endosome with lysosomes, protecting itself from enzymatic destruction. Hiding from host attack by antibody or cell mediated defenses, the EB reorganizes into the replicative form, the reticulate body (RB). RBs successfully parasitize the host cell and divide and multiply. As the RB divides by binary fission, it fills the endosome, now a cytoplasmic inclusion, with its progeny. After 48 to 72 hours, multiplication ceases, and nucleoid condensation occurs as the RBs transform to new infectious EBs. The EBs are released from the cell by cytolysis [25]; by a process of exocytosis [26]; or by extrusion of the whole inclusion [26], leaving the host cell intact. The last-mentioned process may explain the frequency of asymptomatic or subclinical chlamydial infections. Release of the infectious EBs allows infection of new host cells to occur.

# PATHOGENESIS

## CONJUNCTIVITIS

Chlamydiae replicate extensively in epithelial cells of the conjunctiva and cause considerable cell damage. The inflammatory reaction consists mostly of polymorphonuclear leukocytes. Conjunctivitis in most untreated patients resolves spontaneously during the first few months of life. Occasionally, infants maintain persistent conjunctivitis, and pannus formation (neovascularization of the cornea) and scarring typical of trachoma have been reported [2,27]. Loss of vision is rare. Micropannus and some scarring may occur in infants if they are not treated within the first 2 weeks of the disease [28]. If treated early, no ocular sequelae develop.

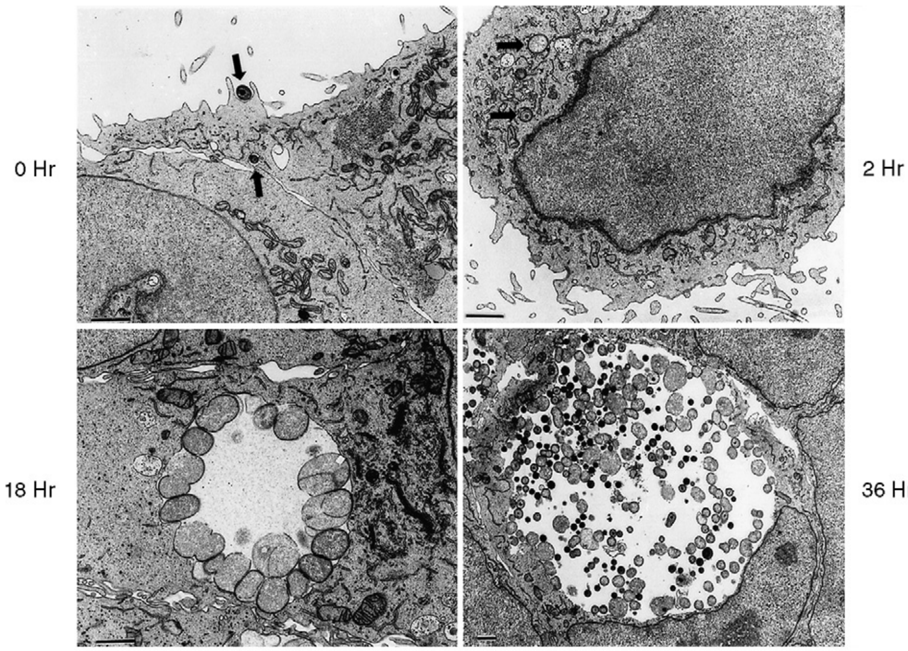

**FIGURE 19–1** ***Chlamydia trachomatis* developmental cycle.** Infection is initiated by elementary bodies (EBs). *0 Hr*, Immediately after endocytosis. EBs are found within tightly associated membrane vesicles. *2 Hr*, Within a few hours, EBs differentiate into larger, metabolically active reticulate bodies (RBs). *18 Hr*, As RBs multiply, inclusion increases in size to accommodate bacterial progeny. RBs are typically observed juxtaposed to inclusion membrane. *36 Hr*, As infection progresses, increasing numbers of chlamydiae are observed unattached in interior of inclusion. These unattached organisms are, for the most part, EBs and intermediate developmental forms. EBs accumulate within inclusion even as RBs, still associated with inclusion membrane, continue to multiply, until cell undergoes lysis at 40 to 48 hours after infection. *(From Stephens RS [ed]. Chlamydia: Intracellular Biology, Pathogenesis, and Immunity. Washington, DC, ASM Press, 1999, p 102.)*

## PNEUMONIA

The nasopharynx is the most frequent site of perinatally acquired chlamydial infection, with approximately 70% of infected infants having positive cultures at that site [29]. Most of these infections are asymptomatic and may persist for 29 months [30]. Chlamydial pneumonia develops in only about 30% of infants with nasopharyngeal infection. Conjunctivitis is not a prerequisite for development of pneumonia.

# PATHOLOGY

In ICN, the affected conjunctiva is highly vascularized and edematous. Inclusions are found in the conjunctival epithelial cells. There is a massive infiltration of polymorphonuclear leukocytes, and pseudomembrane formation may occur. Lymphoid follicles, such as are seen in adults or older children with chlamydial infection of the conjunctiva, are not usually observed until the disease has been active for 1 or 2 months. Because ICN spontaneously resolves by that time in most infants, lymphoid follicles are not commonly observed.

Because pneumonia is rarely fatal, and in most infants the course is relatively benign, there has been little occasion to obtain lung specimens. When lung specimens have been obtained, no characteristic features have been described. Biopsy material has shown pleural congestion and alveolar and bronchiolar mononuclear cell infiltrates with eosinophils and focal aggregations of neutrophils [31,32].

# CLINICAL MANIFESTATIONS

The principal clinical manifestations in infants are ICN, occurring in the first 3 weeks of life, and pneumonia, which occurs within the first 3 months.

## CONJUNCTIVITIS

ICN usually has an incubation period of 5 to 14 days after delivery or earlier if amniotic membranes ruptured prematurely. Approximately one third of infants exposed to chlamydiae during vaginal delivery develop conjunctivitis [33]. Disease manifestations vary widely and range from mild conjunctival injection with scant mucoid discharge to severe mucopurulent conjunctivitis with chemosis and pseudomembrane formation. The eyelids swell, and the conjunctivae become injected and swollen (Fig. 19–2). The "pseudomembrane" consists of inflammatory exudate that adheres to the inflamed surface of the conjunctiva. Except for micropannus formation, the cornea is usually spared. Evaluation of 37 Dutch infants who tested positive for *Chlamydia* revealed mucopurulent eye discharge as the presenting symptom for 35 (95%), swelling of the eyelids for 27 (73%), and conjunctival erythema for 24 (65%); bilateral eye involvement was observed in 27 infants (73%). Presenting symptoms were similar in a group of 22 infants diagnosed with other bacterial pathogens [20].

## PNEUMONIA

Neonatal chlamydial pneumonia was first reported in 1975, and the characteristic clinical picture was described in 1977 [3,34]. Most infants with chlamydial pneumonia are symptomatic before the 8th week of life with the insidious development of nasal obstruction or discharge or both, tachypnea, and a repetitive staccato cough. Some infants may have symptoms the 2nd week of life, initially involving the upper respiratory tract. Characteristically, infants have been symptomatic for 3 or more weeks before presentation. Most are only moderately ill and are afebrile. A history or presence of conjunctivitis can be elicited in half the cases [35]. Some infants may develop apnea. Crepitant inspiratory rales are commonly heard. Expiratory wheezes are distinctly uncommon.

Hyperinflation of the lungs usually accompanies the infiltrates seen on chest radiographs. Infiltrates are most commonly bilateral and interstitial; reticulonodular patterns and atelectasis have also been described [36]. Possible laboratory findings include a distinctive peripheral eosinophilia (>400 cells/mm$^3$), mild arterial hypoxemia, and elevated serum immunoglobulins. Untreated disease can linger or recur. In very young infants, infection may be more severe and associated with apnea.

**FIGURE 19–2** Infant with chlamydial conjunctivitis. *(From Long S, Pickering LK, Prober CG [eds]. Principles and Practice of Pediatric Infectious Diseases. New York, Churchill Livingstone, 2003, p 904.)*

## PERINATAL INFECTIONS AT OTHER SITES

Infants born to mothers infected with *C. trachomatis* may also become infected in the rectum and urogenital tract [37]. Although these infections are generally asymptomatic, they may persist for 3 years [37]. Consequently, differentiating infection acquired perinatally from infection resulting from sexual abuse can be particularly difficult in young children.

# DIAGNOSIS

## CONJUNCTIVITIS

Several nonculture methods are approved by the U.S. Food and Drug Administration (FDA) for the diagnosis of ICN. These include enzyme immunoassays, specifically, Chlamydiazyme (Abbott Diagnostics, Chicago, IL) and MicroTrak EIA (Genetic Systems, Seattle, WA) and direct fluorescent antibody assays using fluorescein-conjugated monoclonal antibodies to stain chlamydial EBs in a smear, including Syva MicroTrak (Genetic Systems) and Pathfinder (Sanofi-Pasteur, Chaska, MN). These tests perform well on conjunctival specimens, with sensitivities of greater than 90% and specificities of 95% or greater compared with culture [38–40].

For resource-poor settings, a useful diagnostic method is examination of Giemsa-stained conjunctival scrapings for the presence of blue-stained intracytoplasmic inclusions within epithelial cells. The sensitivity of the test varies from 22% to 95% depending on the technique of specimen collection and the examiner's expertise. This method also allows visualization of bacteria, such as gonococci, and of cytologic findings suggesting viral infection. Isolation of chlamydiae from conjunctival scrapings inoculated into tissue cell culture is a more reliable, although more costly, method of diagnosis. Serologic diagnosis of chlamydial conjunctivitis (in contrast to pneumonia) is unreliable because of the presence of maternally transmitted IgG antibody and the unreliable appearance of IgM antibody in this infection.

Even if a firm diagnosis of chlamydial conjunctivitis is established, one must be mindful of the possibility of a dual infection, particularly with *Neisseria gonorrhoeae*. For this reason, appropriate stain and culture of the conjunctival exudate should be obtained.

Highly sensitive nucleic acid amplification tests (NAATs) are commercially available for diagnosis of genital chlamydial infection in adolescents and adults [41,42]. NAATs have FDA approval for cervical swabs from women, urethral swabs from men, and urine from men and women. These tests have high sensitivity, perhaps even detecting 10% to 20% more cases of genital chlamydial infection than possible with culture, while retaining high specificity [43]. Information on the use of NAATs in children is limited, but preliminary data suggest that PCR is equivalent to culture for the detection of *C. trachomatis* in the conjunctiva and nasopharynx of infants with conjunctivitis [44]. More recent data indicate NAATs are significantly more sensitive than cell culture for diagnosis of *C. trachomatis* from genital and nongenital specimens [45].

## PNEUMONIA

Enzyme immunoassays and direct fluorescent antibody assays for *Chlamydia* do not perform well with nasopharyngeal specimens and are not approved for this purpose. The definitive diagnosis of pneumonia can be made by culture of the organism from the respiratory tract. *Chlamydia* culture has been defined by the U.S. Centers for Disease Control and Prevention (CDC) as isolation of the organism in tissue culture and confirmation by microscopic identification of the characteristic inclusions by fluorescent antibody staining [46]. The likelihood of obtaining a positive culture is enhanced by deep suction of the trachea or by collecting a nasopharyngeal aspirate, rather than obtaining a specimen with a swab [3,47]. An acute microimmunofluorescence serum titer of *C. trachomatis*–specific IgM of 1:32 or greater is also diagnostic. In contrast, IgG is not diagnostic because passively transferred maternal antibody may persist at high titers for months. The serologic test of choice is the microimmunofluorescent procedure of Wang and colleagues [48], in which EBs are used as antigen. Only a few clinical reference laboratories perform this test.

Indirect evidence of chlamydial pneumonia includes hyperinflation and bilateral diffuse infiltrates on chest radiographs, eosinophilia of 0.3 to $0.4 \times 10^9$/L (300 to 400/μL) or more in peripheral blood counts, and increased total serum IgG (>5 g/L [>500 mg/dL]) and IgM (>1.1 g/L [>110 mg/dL]) concentrations. The absence of any or all of these findings does not exclude the diagnosis, however.

# DIFFERENTIAL DIAGNOSIS

## CONJUNCTIVITIS

ICN must be distinguished from conjunctivitis produced by pyogenic bacteria, particularly *N. gonorrhoeae*. Gonococcal ophthalmia usually occurs earlier, about 2 to 5 days after birth, although overlap in age at onset can occur. Gonococcal disease is usually more rapidly progressive than disease caused by *C. trachomatis*. Gonococcal infection can be diagnosed presumptively by examination of the Gram-stained smear of the exudate and confirmed by culture of the exudate. Staphylococcal conjunctivitis is usually acquired nosocomially from the nursery environment. It is characterized more by purulent discharge than by redness. This and other forms of pyogenic conjunctivitis—which may be due to *S. pneumoniae*, *Haemophilus* species, or gram-negative bacteria such as *Pseudomonas aeruginosa*—can be appropriately diagnosed by Gram stain and culture of the exudate.

Of viral infections, neonatal herpes simplex (see Chapter 26) is the most important. This disease is characterized by involvement of the skin and the eye, vesicle formation, and sometimes corneal involvement. Adenovirus infection of the newborn is very rare, but has been described.

Chemical conjunctivitis related to instillation of silver nitrate at birth may also produce marked redness and a purulent discharge. These symptoms start on the first day of life and disappear after a few days, however, distinguishing this entity from a chlamydial infection.

## PNEUMONIA

An afebrile, tachypneic infant presenting with a staccato cough in the first 3 months of life is very likely to have chlamydial disease. Cytomegalovirus may produce an interstitial pneumonia in preterm newborns who receive transfusions from cytomegalovirus-positive donors; however, it often produces signs and symptoms in other organ systems. Congenital infections with the rubella virus and

*Toxoplasma gondii* also produce multiorgan involvement, as does perinatal infection with herpes simplex virus. Adenovirus or parainfluenza virus infection may produce an interstitial pneumonia, but without the characteristic staccato cough or eosinophilia. Respiratory syncytial virus is a common cause of pneumonia in early infancy, but it often produces fever in the early stages, and wheezing because of airway obstruction is common with this illness. Respiratory syncytial virus is not associated with eosinophilia. Respiratory syncytial virus infection can be rapidly diagnosed by performing an enzyme immunoassay on a nasopharyngeal wash specimen.

Many pyogenic bacteria may produce lower respiratory tract infections in infancy. Group B streptococci, *Streptococcus pneumoniae*, *Staphylococcus aureus*, *Haemophilus influenzae*, and coliform bacteria are the most common. These patients are generally much sicker, are more toxic and febrile, and have pulmonary consolidation rather than an interstitial infiltrate. *Bordetella pertussis* classically causes a paroxysmal cough with an inspiratory whoop and post-tussive emesis. Lymphocytosis is seen with whooping cough, and apnea occurs in infants younger than 6 months of age. Infants with *Pneumocystis jiroveci* pneumonia develop a characteristic syndrome of subacute diffuse pneumonitis with dyspnea at rest, tachypnea, oxygen desaturation, nonproductive cough, and fever.

## PROGNOSIS

### CONJUNCTIVITIS

If untreated, ICN may persist for many weeks, but it usually resolves spontaneously without complications. The scarring that occurs in trachoma that leads to lid deformities is not seen. Superficial corneal vascularization and conjunctival scar formation can occur, however [27,28,49].

### PNEUMONIA

Untreated infants are usually ill for several weeks, with frequent cough, poor feeding, and poor weight gain. A few infants require oxygen, and fewer require ventilatory support. Beem and colleagues [50] found in a series of 11 infants that the total course of illness is 24 to 61 days, with an average of 43 days; mortality is exceptionally rare. Follow-up evaluation of a small cohort of children who had *C. trachomatis* pneumonia in infancy showed an increased prevalence of chronic cough and abnormal lung function compared with age-matched controls [51].

## THERAPY

Topical treatment of inclusion conjunctivitis is not recommended primarily because of failure to eliminate concurrent nasopharyngeal infection. Recommended therapy for conjunctivitis is oral erythromycin, 50 mg/kg/day in four divided doses for 14 days. Topical treatment of conjunctivitis is ineffective and unnecessary. The failure rate is around 20%, and a second course of therapy may be required [29,52]. Problems with compliance and tolerance are frequent. Oral sulfonamides may be used after the immediate neonatal period for infants who do not tolerate erythromycin.

Chlamydial pneumonia is treated with oral azithromycin, 20 mg/kg, once daily for 3 days, or erythromycin, 50 mg/kg/day in four divided doses for 14 days. An oral sulfonamide is an alternative for infants who do not tolerate macrolides. There is convincing evidence that this treatment shortens the clinical course of pneumonia and eliminates the organism from the respiratory tract. Beyond specific antimicrobial therapy, infants require standard support measures, with attention to nutrition and to fluid status. Oxygen and ventilatory therapy may be required in a few cases. A specific diagnosis of *C. trachomatis* infection in an infant should prompt treatment of the mother and sexual partners.

An association between orally administered erythromycin and infantile hypertrophic pyloric stenosis (IHPS) has been reported in infants younger than 6 weeks of age who were given the drug for prophylaxis after nursery exposure to pertussis [53,54]. The risk of IHPS after treatment with other macrolides (e.g., azithromycin dihydrate and clarithromycin) is unknown. Because confirmation of erythromycin as a contributor to cases of IHPS requires additional investigation and because alternative therapies are not as well studied, the American Academy of Pediatrics continues to recommend use of erythromycin for treatment of *C. trachomatis* in infants. Parents of infants treated with erythromycin should be informed about the signs and potential risks of developing IHPS. Cases of pyloric stenosis after use of oral erythromycin should be reported to the FDA as an adverse drug reaction. One small study suggests that a short course of orally administered azithromycin, 20 mg/kg/day, one dose daily for 3 days, may be effective [19].

Prophylactic therapy of infants born to mothers known to have untreated chlamydial infection is not indicated because the efficacy of such prophylaxis is unknown. Infants should be monitored for signs of infection and to ensure appropriate treatment if infection develops. If adequate follow-up cannot be ensured, prophylaxis may be considered.

## PREVENTION

Because *C. trachomatis* infections are transmitted vertically from mother to infant during delivery, an effective prevention measure is screening and treatment of pregnant women for *C. trachomatis* infection before delivery. The CDC currently recommends screening all pregnant women during their first prenatal visit and during the third trimester if high risk (<25 years old or other risk factors such as new or multiple sexual partners) [46]. Erythromycin base (2 g/day in four divided doses) and amoxicillin (1.5 g/day in three divided doses) for 7 days are recommended treatment regimens for pregnant women. Half doses of erythromycin daily for 14 days may be given in pregnant women who are intolerant of the full dose regimen. Because these regimens are not highly efficacious, a second course of therapy may be needed. Azithromycin (1 g orally as a single dose) is an alternative; preliminary data suggest it is safe and effective [55]. Doxycycline and ofloxacin are contraindicated during pregnancy.

Ocular prophylaxis with topical erythromycin or tetracycline has reduced the incidence of gonococcal ophthalmia, but does not seem to be effective against *C. trachomatis* [56]. The only means of preventing chlamydial infection of the newborn is treatment of infected mothers before delivery.

Ongoing efforts to develop a *C. trachomatis* vaccine to protect persons from genital tract infection have concentrated primarily on the use of peptides derived from MOMP or recombinant synthetic MOMP polypeptides as immunogens. Future work may incorporate molecular technology and our increasing understanding of the host response to chlamydiae to develop one or more new vaccines. Stimulation of long-term mucosal immunity in the genital tract is a challenge; it is unclear whether all genital infections could be prevented, or whether only more invasive disease, such as salpingitis, might be preventable using vaccine technology.

CHAPTER

20

# Mycoplasmal Infections

R. Doug Hardy ✪ Octavio Ramilo

## CHAPTER OUTLINE

Mycoplasmas are prokaryotes of the class Mollicutes and represent the smallest known free-living organisms. Their small size of 150 to 350 nm is more on the order of viruses than of bacteria. They lack a cell wall and are bound by a cell membrane. Many of the biologic properties of mycoplasmas are due to the absence of a rigid cell wall, including resistance to β-lactam antibiotics and marked pleomorphism among individual cells. The mycoplasmal cell membrane contains phospholipids, glycolipids, sterols, and various proteins. Mycoplasmas are able to grow in cell-free media and possess RNA and DNA. The entire genomes of many of the *Mycoplasma* species have been sequenced and have been found to be among the smallest of prokaryotic genomes; the *Mycoplasma genitalium* genome consists of only 580,070 DNA base pairs. The elimination of genes related to synthesis of amino acids, fatty acid metabolism, and cholesterol necessitates a parasitic dependence on their host for exogenous nutrients, such as nucleic acid precursors, amino acids, fatty acids, and sterols. In mammals, *Mycoplasma* species most commonly colonize mucosal surfaces, such as the respiratory and genital tracts. At least 16 different species of Mollicutes colonize the mucosa of humans.

*Ureaplasma* species and *Mycoplasma hominis* are the mycoplasmas most commonly isolated from the genital tract of women and are associated with maternal and fetal infection. This chapter focuses on these two species in the maternal and fetal, neonatal, and very young infant populations. Mycoplasmal illnesses in other populations, such as immunocompromised older children and nonpregnant adults, are not discussed. *Mycoplasma pneumoniae*, *M. genitalium*, and *Mycoplasma fermentans* are mentioned briefly.

The originally identified species *Ureaplasma urealyticum* has been divided into two species, *Ureaplasma parvum* and *Ureaplasma urealyticum*, based on 16S rRNA sequences; the 14 described serovars were reassigned, with *U. parvum* containing 4 serovars (1, 3, 6, and 14) and *U. urealyticum* containing the remaining 10 serovars (2, 4, 5, 7, 8, 9, 10, 11, 12, and 13). Most of the available literature simply refers to *U. urealyticum* without differentiation into *U. parvum* or *U. urealyticum*. A few more recent investigations distinguish between *U. parvum* and *U. urealyticum* in their results, but not enough data are available to determine if the two species or 14 serovars differ in pathogenicity. In this chapter, *Ureaplasma* is used to refer to *U. parvum* and *U. urealyticum* without differentiation.

## *UREAPLASMA* AND *MYCOPLASMA HOMINIS*: COLONIZATION AND DISEASES OF THE URINARY AND REPRODUCTIVE TRACTS IN ADULTS

### COLONIZATION

*Ureaplasma* and *M. hominis* are commensal organisms in the lower female genital tract. Colonization of the female lower urogenital tract by *Ureaplasma* and *M. hominis* generally occurs as a result of sexual activity. Sexual contact is the major mode of transmission of these organisms, and colonization increases dramatically with increasing numbers of sexual partners [1–3].

In an asymptomatic woman, these mycoplasmas may be found throughout the lower urogenital tract, including the external cervical os, vagina, labia, and urethra [4,5]. The vagina yields the largest number of organisms, followed by the periurethral area and the cervix [5]. *Ureaplasma* is isolated less often from urine than from the cervix, but *M. hominis* is present in the urine and in the cervix with approximately the same frequency. In asymptomatic men, mycoplasmas also have been isolated from urine, semen, and the distal urethra [6].

DOI: 10.1016/B978-1-4160-6400-8.00020-1

*Ureaplasma* can be isolated from the vagina of 40% to 80% of sexually active, asymptomatic women; *M. hominis* is found in 21% to 70%. Both microorganisms can be found concurrently in 31% to 60% of women [7,8]. In men, colonization with each is less prevalent. In women, colonization has been linked to younger age, lower socioeconomic status, multiple sexual partners, black ethnicity, oral contraceptive use, and recent antimicrobial therapy [3,9]. Additionally, mycoplasmas are prevalent in the lower genital tract of pregnant women [7,10,11]. When genital mycoplasmas are present at the first prenatal visit, usually they persist throughout the pregnancy. Studies suggest that postmenopausal women are infrequently colonized with genital mycoplasmas [12].

## URINARY TRACT

Three disease associations have been established for *Ureaplasma* and *M. hominis* in the urinary tract: urethritis in men caused by *Ureaplasma*, urinary calculi caused by *Ureaplasma*, and pyelonephritis caused by *M. hominis* [13]. Intraurethral inoculation of human volunteers and nonhuman primates with *Ureaplasma* produces urethritis [13]. Serologic studies and clinical responsiveness in antimicrobial treatment trials also support a causative role of this organism in urethritis [13]. The common presence of ureaplasmas in the urethra of asymptomatic men suggests either that only certain serovars of ureaplasmas are pathogenic or that predisposing factors, such as lack of mucosal immunity, must exist in individuals in whom symptomatic infection develops. Alternatively, disease may develop only on initial exposure to ureaplasmas. *Ureaplasma* also has been implicated in urethroprostatitis and epididymitis [14].

*Ureaplasma* has been shown to have a limited role in the production of urinary calculi. *Ureaplasma* produces urease, which splits urea into ammonia and carbon dioxide, and has been shown to induce crystallization of struvite and calcium phosphates in artificial urine in vitro, showing the capacity of the pathogen to induce stone formation [15,16]. Renal calculi have been induced experimentally by inoculation of pure cultures of *Ureaplasma* directly into the bladder and renal pelvis of rats. *Ureaplasma* has been isolated from stones recovered by surgery in 6 of 15 patients. In four of the six patients, no other urease-producing organisms were isolated either in the stone or in urine sampled from the renal pelvis. *Proteus mirabilis* is the most common infectious cause of similar stones in humans. The frequency with which *Ureaplasma* reaches the kidney, the predisposing factors that allow this to occur, and the relative frequency of renal calculi induced by this organism compared with that of calculi induced by other organisms is unknown.

Even with the high incidence of *M. hominis* in the lower urogenital tract, this organism has been isolated from the upper urinary tract only in patients with symptoms of acute infection [17]. In one study, *M. hominis* was recovered from samples of ureteral urine collected during surgery from 7 of 80 patients (4 in pure culture) with acute pyelonephritis, and in a second study from 3 of 18 patients with acute exacerbation of chronic pyelonephritis. *M. hominis* was not found in the upper urinary tract of 22 patients with chronic pyelonephritis without acute exacerbation or in 60 patients with noninfectious urinary tract disease.

## REPRODUCTIVE TRACT

*M. hominis* is considered an etiologic agent of pelvic inflammatory disease [18–21]. Inoculation of *M. hominis* into fallopian tubes of primates induces parametritis and salpingitis within 3 days [22], whereas inoculation of human fallopian tube explants produces ciliostasis [23]. The organism has been isolated in pure cultures from the fallopian tubes of approximately 8% of women with salpingitis diagnosed by laparoscopy, but not in any women without salpingitis [18]. The organism also can be isolated from the endometrium. A role for this organism in cases of pelvic inflammatory disease not associated with either *Neisseria gonorrhoeae* or *Chlamydia trachomatis* is supported by significant increases in specific antibodies to *M. hominis* [20]. *Ureaplasma* is not considered to be a cause of pelvic inflammatory disease [14].

# CHORIOAMNIONITIS, CLINICAL AMNIONITIS, AND MATERNAL SEPTICEMIA

## HISTOLOGIC CHORIOAMNIONITIS

Isolation of *Ureaplasma*, but not *M. hominis*, from the chorioamnion uniformly has shown a significant association with histologic chorioamnionitis [24–30]. Studies in which extensive culture for other agents was performed reported that women whose amniotic membranes contained *Ureaplasma* were more likely to have histologic evidence of chorioamnionitis than women without *Ureaplasma*, even after adjusting for duration of labor, premature rupture of membranes, duration of membrane rupture, and presence of other bacteria [27]. *Ureaplasma* in the chorioamnion was found to be significantly associated with histologic chorioamnionitis in the presence of intact membranes when delivery was by cesarean section [31]. In some cases, *Ureaplasma* was the only organism isolated. Case reports [25,32,33] indicate that *Ureaplasma* can persist in the amniotic fluid for 7 weeks in the presence of an intense inflammatory response and in the absence of ruptured membranes or labor and can be isolated as a single microorganism when cultures for multiple agents are performed. These findings show that ureaplasmas can produce histologic evidence of chorioamnionitis.

## INFECTION OF THE AMNIOTIC FLUID AND CLINICAL AMNIONITIS

Although *Ureaplasma* and *M. hominis* can invade the amniotic fluid at 16 to 20 weeks of gestation in the presence of intact membranes and in the absence of other microorganisms, these infections tend to be clinically silent and chronic (Fig. 20–1) [25,32]. *Ureaplasma* and *M. hominis* have been isolated more frequently from the chorioamnion than from the amniotic fluid. Isolation of organisms from the chorioamnion or amniotic fluid has been

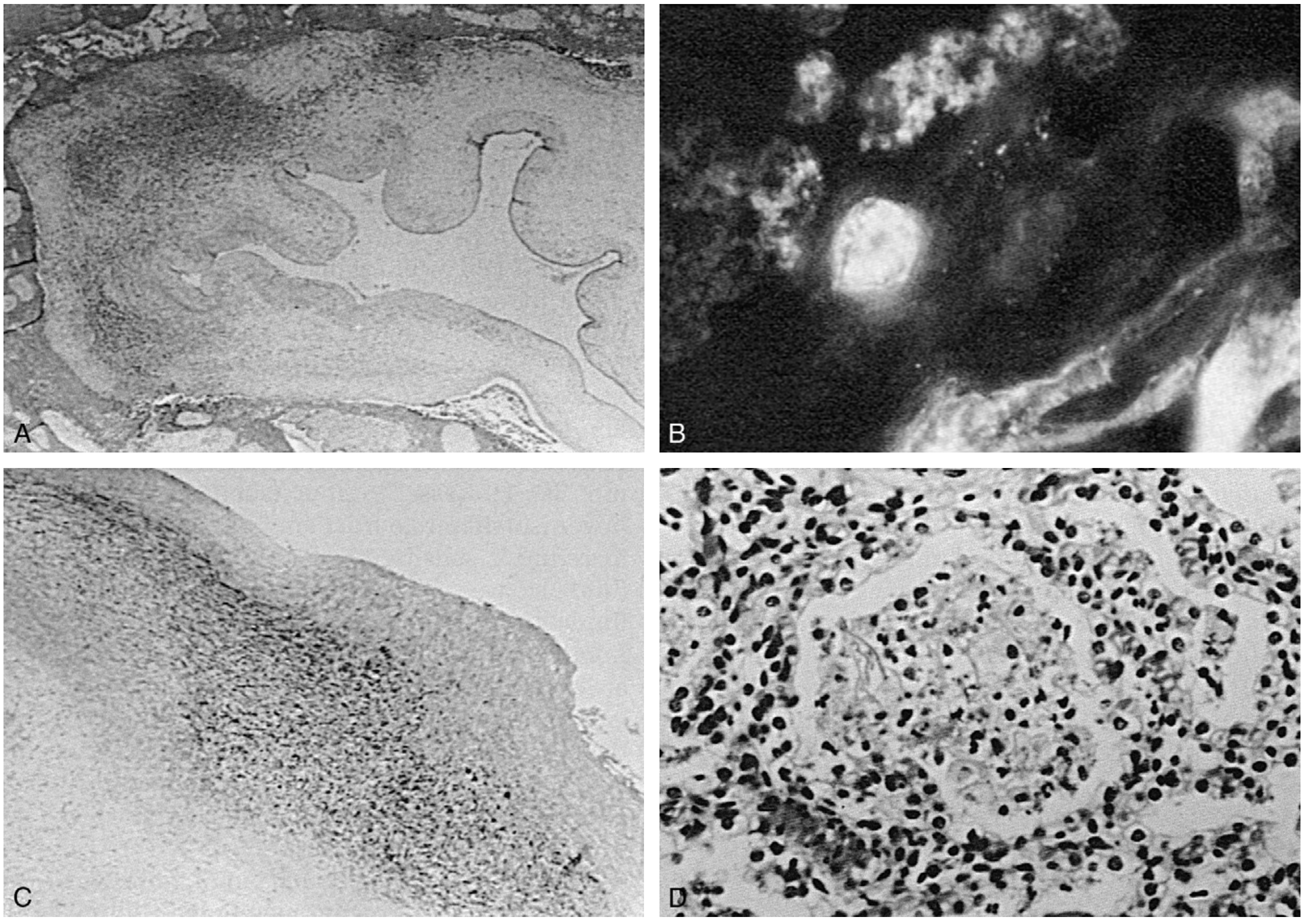

**FIGURE 20–1** **A,** Section of placenta at 24 weeks of gestation showing extensive inflammation in amnion and chorion. (Magnification 25×.) *Ureaplasma* was isolated from amniotic fluid 7 weeks before delivery and from multiple fetal organs at postmortem examination. **B,** Adjacent section of placenta stained with rabbit anti-*Ureaplasma* serovar 1 serum and reacted with fluorescein-labeled goat anti-rabbit IgG. (Magnification 750×.) **C,** Photomicrograph of umbilical cord from same case as in **A** and **B** shows extensive inflammation. (Magnification 25×.) **D,** Photomicrograph of lung tissue shows histologic evidence of pneumonia. (Magnification 50×.)

significantly associated with histologic evidence of chorioamnionitis, but not with clinical amnionitis [31]. Ureaplasmas can be detected in the amniotic fluid in 50% of asymptomatic and symptomatic individuals [34]. These reports indicate that the role of *Ureaplasma* in clinical amnionitis is unclear.

In an investigation by Yoon and colleagues [35], amniocentesis was performed in 154 patients with preterm premature rupture of membranes. Amniotic fluid was cultured for aerobic and anaerobic bacteria and for mycoplasmas. Polymerase chain reaction (PCR) assay for *Ureaplasma* also was performed on the fluid. These investigators found that amniotic fluid culture for mycoplasmas missed 42% of cases identified as positive by *Ureaplasma* PCR assay. Patients with a negative result on amniotic fluid culture for *Ureaplasma* but a positive result on PCR assay had a significantly shorter interval from amniocentesis to delivery, higher amniotic fluid interleukin-6 concentrations, and higher white blood cell counts compared with patients without detection of *Ureaplasma* by culture or PCR assay. Subsequently, in a similar investigation by the same group [36] in 257 patients with preterm labor and intact membranes, significant findings were similar except that the prevalence of *Ureaplasma* was lower.

The detection of *M. hominis* does not correlate with clinical symptoms. *M. hominis* commonly invades the chorioamnion and amniotic fluid, but such invasion rarely occurs in the absence of other organisms, particularly ureaplasmas. It is unclear whether this organism alone is a cause of histologic chorioamnionitis or clinical amnionitis [31].

## POSTPARTUM AND POSTABORTAL FEVER

*M. hominis* [37–40] and *Ureaplasma* [41,42] have been isolated from blood cultures from women with postpartum fever and septic abortion. Serologic investigations indicate that *M. hominis* is a common cause of postpartum fever, as shown by a fourfold or greater increase in mycoplasmacidal antibody titer [43]. In a study at Boston City Hospital [44], blood was obtained from 327 women shortly after vaginal delivery. Of these 327 women, 10 had blood cultures that grew *M. hominis*, *Ureaplasma*

grew in 15, and *M. hominis* and *Ureaplasma* were isolated in 1 woman. The frequency of isolation of mycoplasmas was inversely related to the interval between delivery and the time at which the blood was obtained for culture. Twenty women whose blood culture grew mycoplasmas at the time of delivery were reevaluated with a second culture 1 or more days later; a positive result was obtained on the second blood culture in only 1 of the 20 women. Pathogenic bacteria were cultured from the blood of 16 of the 327 women, including 4 of the 11 women with *M. hominis*, but none from the women with *Ureaplasma*.

In a prospective study of 620 blood cultures from febrile obstetric patients [45], *Ureaplasma* was the second and *M. hominis* the third most common microorganism isolated. All specimens were obtained during febrile postpartum or postabortum episodes. Mycoplasmas were isolated on numerous occasions from blood drawn more than 2 days after the procedure. Endometritis or histologically documented chorioamnionitis was present in half of the patients, and fever persisted after delivery or abortion in many of the cases despite administration of antimicrobial agents directed at organisms other than mycoplasmas. Fever resolved after tetracycline therapy.

It has been shown that colonization of the chorioamnion with ureaplasmas in women with intact membranes undergoing cesarean delivery is a significant and independent predictor of ensuing endometritis [46]. Endometritis occurred in 28% of women with ureaplasmas isolated from the chorioamnion at cesarean delivery compared with only 8.4% if the culture result was negative and 8.8% if only bacteria but no ureaplasmas were isolated.

Roberts and associates [47] found ureaplasmas to be the most common microorganism isolated from postcesarean wound infections. Of 47 cultures with a positive result from 939 wounds, ureaplasmas were recovered from 29. Additionally, one third of the cultures positive for ureaplasmas yielded no other microorganisms. *M. hominis* has been recovered from the joint fluid of women postpartum. These women had been febrile during the immediate postpartum period, and signs of arthritis developed 7 days to 3 weeks after delivery [48]. Cases of postpartum pneumonia with isolation of *M. hominis* from pleural fluid and cases of *M. hominis* wound infections after cesarean section also have been reported [49–52].

Andrews and coworkers [53] performed a randomized, double-blind, placebo-controlled trial in 597 women to compare rates of postcesarean endometritis after prophylaxis with cefotetan versus cefotetan plus doxycycline and azithromycin. The frequency of postcesarean endometritis and wound infection was significantly lower in the group that received cefotetan plus doxycycline and azithromycin. The investigators concluded that this extended-spectrum antibiotic prophylaxis regimen, with activity against mycoplasmas, reduced the frequency of postcesarean endometritis and wound infection. *Mycoplasma* cultures were not obtained in this investigation, however, so it is unclear that the improved outcome was specifically due to the addition of doxycycline and azithromycin prophylaxis aimed at *Mycoplasma* infections versus other synergistic antibacterial or immunomodulatory effects of these agents.

# ADVERSE PREGNANCY OUTCOME

## FETAL LOSS

Although studies have found the presence of *Ureaplasma* and *M. hominis* in the genital tract to be significantly associated with spontaneous abortion and early pregnancy loss [54], their actual role in these events is uncertain. Both organisms have been isolated from the lungs, brain, heart, and viscera of aborted fetuses and stillborn infants, in some cases in the presence of an inflammatory response and in the absence of other organisms [25,29,55,56]. In these cases, it was unclear whether death of the fetus occurred before these organisms "invaded." *Ureaplasma* has been found more frequently in the products of early abortions and mid-trimester fetal losses than in products of induced abortions [57,58]. *Ureaplasma* has been isolated more frequently from the placentas of aborted fetuses than from controls [26,29].

Although rates of isolation of ureaplasmas from the lower genital tract of women with habitual abortion are not different from those of normal controls, ureaplasmas are isolated more frequently from the endometrium of women with habitual abortion [57,58]. When only patients with a positive result on cervical culture are considered, no higher endometrial colonization rates are found [59]. Antibody titers to *Ureaplasma* are higher in mothers with a history of fetal loss [60]. These epidemiologic studies are difficult to interpret, however, because the comparability of the various groups of women is uncertain, and the role of other potential infectious agents was not always taken into account.

Isolation of *Ureaplasma* from amniotic fluid in pure culture from women with intact membranes and subsequent fetal loss in the presence of histologic chorioamnionitis has been reported [25,32,33]. Berg and associates [61] performed a retrospective analysis of 2718 amniocentesis specimens obtained for genetic indications and cultured for *Ureaplasma* and *M. hominis*. Of the 2718 patients, 49 (1.8%) patients were found to be positive for one or both organisms. Of 43 patients who could be evaluated, 35 were given oral erythromycin at the discretion of the physician caring for the patient. Rates of mid-trimester loss were 11.4% and 44.4% ($P = .04$) in the treated and untreated groups. This study showed that treatment of amniotic mycoplasmal colonization with erythromycin may decrease mid-trimester losses. Prospective controlled trials are necessary to validate this hypothesis.

## PRETERM BIRTH

Multiple studies involving almost 12,000 patients have been conducted to evaluate the association of cervical ureaplasmal infection with prematurity [62,63]. The evidence suggests no consistent relationship between the presence of *Ureaplasma* in the lower genital tract of the mother and prematurity or low birth weight in the infant.

At least six prospective studies have evaluated the role of ureaplasmal infection of the amniotic fluid in the etiology of prematurity. Three of these studies investigated the outcome of pregnancy when ureaplasmas were detected at the time of genetic amniocentesis at 12 to 20 weeks of gestation, when membranes were intact and when labor had

not begun [25,32,64]. In an investigation by Cassell and colleagues [25], two infants with *Ureaplasma* isolated from amniotic fluid were born preterm; both infants died, and both had evidence of pneumonia. *Ureaplasma* was isolated in pure culture at postmortem examination in both cases. In a study by Gray and associates [32], 7 of 10 patients from whom ureaplasmas were isolated by culture of the amniotic fluid subsequently aborted within 4 to 7 weeks after amniocentesis and at less than 25 weeks of gestation. The three remaining infants were born at less than 37 weeks of gestation, and two of these died. Histologic evidence of chorioamnionitis was present in all 10 placentas, and histologic evidence of pneumonia was present in all eight fetuses. Placentas grew *Ureaplasma*, but results were negative for cultures of all other microorganisms in six of seven evaluated at delivery and in four of the six fetal lungs that were evaluated.

The third and largest investigation by Gerber and coworkers [64] used PCR assay and detected *Ureaplasma* in 29 of 254 (11.4%) amniotic fluid specimens. As might be expected, a higher percentage of *Ureaplasma*-positive amniotic fluid samples were found in this study that used PCR than in previous investigations that relied solely on culture. Subsequent preterm labor occurred in 17 (58.6%) *Ureaplasma*-positive women compared with 10 (4.4%) women whose cultures were *Ureaplasma*-negative ($P < .0001$). Preterm birth occurred in seven (24.1%) *Ureaplasma*-positive women compared with one (0.4%) *Ureaplasma*-negative woman ($P < .0001$). *Ureaplasma*-positive women had a higher prevalence of preterm labor in a prior pregnancy (20.7%) than the *Ureaplasma*-negative women (2.7%; $P < .0008$).

In contrast to the above-mentioned studies, in the remaining three studies culture of amniotic fluid was performed on women hospitalized with preterm labor and intact membranes. *Ureaplasma* in the amniotic fluid was not consistently associated with preterm birth in these studies [65–67]. In these later studies of women with preterm labor, the mean gestation was 31.5 weeks compared with 12 to 20 weeks of gestation in the previous studies of women with no labor.

A significant relationship between isolation of *Ureaplasma* from the chorioamnion and preterm birth has been documented in three of six prospective studies [26–28, 68–70]. In most patients in these investigations, membrane rupture had occurred, however, which could have led to intrapartum microbial invasion of the chorioamnion, potentially confounding the results even if the duration of membrane rupture is taken into account.

As noted previously, Berg and associates [61] performed a retrospective analysis of 2718 genetic amniocentesis specimens cultured for *Ureaplasma* and *M. hominis*. Of the 2718 specimens, 49 (1.8%) were found to be positive for either organism. Of 43 patients who could be evaluated in this study, 35 received treatment with oral erythromycin. Preterm delivery rates were similar in the treated and untreated groups (19.4% and 20%). The investigators speculated that the lack of a treatment effect may have been due to recolonization with mycoplasmas.

The sum of the evidence suggests that the risk of preterm labor and delivery is increased when ureaplasmas are detected at amniocentesis at 12 to 20 weeks of gestation in women with intact membranes before onset of labor. Otherwise, the association between preterm birth and ureaplasmas is uncertain.

## TRANSMISSION OF *UREAPLASMA* AND *MYCOPLASMA HOMINIS* TO THE FETUS AND NEWBORN

*Ureaplasma* and *M. hominis* can be transmitted to a fetus from an infected woman either in utero or at the time of delivery by passage through a colonized birth canal. The isolation of *Ureaplasma* in pure culture from the chorioamnion, amniotic fluid, and internal fetal organs in the presence of funisitis and pneumonia [25] and a specific IgM response [71] can be taken as evidence that fetal infection can occur in utero. Investigators [72,73] also have found that *Ureaplasma* and *M. hominis* can be isolated from endotracheal specimens collected within 30 minutes to 24 hours after birth from infants who were delivered by cesarean section with intact membranes. It is thought that the acquisition of *Ureaplasma* and *M. hominis* can occur in utero either by an ascending route secondary to colonization of the mother's genital tract or transplacentally from the mother's blood. Each of these organisms has been isolated from maternal and umbilical cord blood at the time of delivery [74,75].

The rate of vertical transmission of *Ureaplasma* and *M. hominis* ranges from 18% to 88% [75–79]. Chua and colleagues [79] prospectively investigated the transmission and colonization of *Ureaplasma* and *M. hominis* from mothers to term and preterm newborns delivered by the vaginal route. The rates of maternal cervical colonization with *Ureaplasma* and *M. hominis* were 57.5% and 15.8%, whereas the rates for isolation of *Ureaplasma* and *M. hominis* from nasopharyngeal secretions of the newborns were 50.8% and 6.6%. The vertical transmission rates were 88.4% for *Ureaplasma* and 42.1% for *M. hominis*. Maternal transmission was not associated with gestational age. In preterm neonates, the isolation of mycoplasmas was not associated with gestational age or birth weight. There was a tendency for *Ureaplasma* to persist in preterm newborns, especially in neonates with birth weight less than 2 kg. Colonization of full-term infants seems to be transient, with a sharp decrease in isolation rates after 3 months of age [80]. In premature infants with ureaplasmal infection, persistence of the organism in the lower respiratory tract and cerebrospinal fluid (CSF) has been documented for weeks to months [72,81].

## PERINATAL *UREAPLASMA* AND *MYCOPLASMA HOMINIS* INFECTION

Many prospective studies based on direct culture of the affected site indicate that *Ureaplasma* and *M. hominis* can cause invasive disease in infants, particularly in infants born prematurely. The presence of mycoplasmas in the chorioamnion or amniotic fluid does not always result in infection of the fetus, however. Similarly, the isolation of mycoplasmas from surface cultures (e.g., eyes, ears, nose, throat, gastric aspirates, vagina) is not indicative of invasive disease.

## PNEUMONIA

Case reports [32,82,83], retrospective studies [84], and prospective studies [25,29,32] indicate an association of *Ureaplasma* with congenital and neonatal pneumonia. The organism has been isolated from affected lungs in the absence of other pathogens, such as chlamydiae, viruses, fungi, and bacteria, in the presence of chorioamnionitis and funisitis [25] and has been shown within fetal membranes by immunofluorescence [25] and in lung lesions by electron and immunofluorescent microscopy [71]. A specific IgM response has been shown in some cases of neonatal pneumonia [71].

In a study of 98 infants [72], respiratory distress syndrome, the need for assisted ventilation, severe respiratory insufficiency, and death were significantly more common in infants born at less than 34 weeks of gestation from whom *Ureaplasma* was recovered from endotracheal aspirates at delivery than in infants with a negative culture result. In another series of 292 infants with birth weights less than 2500 g who were studied by follow-up evaluation for 4 weeks after birth, isolation of *Ureaplasma* from the endotracheal aspirate within 1 week of birth (mean age 1.3 days) was significantly associated with radiographic pneumonia, whereas no such association was found for uninfected infants [85]. *Ureaplasma* was the most common organism isolated (15% of infants) among these 292 patients, and it was isolated in pure culture in 71%.

Cultrera and colleagues [86] investigated for molecular evidence of *U. urealyticum* or *U. parvum* respiratory colonization in preterm infants with or without respiratory distress syndrome. Significantly, 15 of 24 preterm neonates with respiratory distress syndrome and 4 of 26 without respiratory distress syndrome were PCR-positive for *Ureaplasma* ($P < .001$). Of the 15 preterm infants PCR-positive for *Ureaplasma*, 5 had *U. urealyticum* and 10 had *U. parvum* isolated. In this investigation, *Ureaplasma* culture was positive in 5 of 50 subjects compared with 19 of 50 subjects by PCR method ($P < .05$).

Conversely, other investigators have found a possibly protective effect associated with the isolation of *Ureaplasma* from preterm infants. In a prospective consecutive investigation of 143 ventilated newborns born at less than 28 weeks of gestation, Hannaford and coworkers [87] isolated *Ureaplasma* from endotracheal aspirates of 39 (27%) infants. Respiratory distress syndrome occurred significantly less often in infants from whom *Ureaplasma* was isolated than in infants from whom it was not isolated ($P = .002$). In addition, a trend for lower mortality rates in the first 28 days of life was identified among *Ureaplasma*-positive infants. Berger and associates [88] also found an apparently protective effect of *Ureaplasma* isolated from the amniotic cavity at the time of delivery against hyaline membrane disease in infants with a mean gestational age of 29 to 30 weeks, although this was nonsignificant. No increase in acute morbidity or mortality was found to be associated with *Ureaplasma* isolation.

The baboon model of prematurity has been employed to investigate the pathogenicity of *Ureaplasma*. At age 140 days, baboons show physiologic and pathologic characteristics similar to those of human neonates of 30 to 32 weeks of gestation (e.g., they have hyaline membrane disease) [89]. Endotracheal inoculation of premature baboons with *Ureaplasma* isolated from human infants results in histologic pulmonary lesions, including acute bronchiolitis with epithelial ulceration and polymorphonuclear infiltration, that are indistinguishable from those of hyaline membrane disease [90].

Yoder and colleagues [91] performed an investigation in premature baboons that offers an explanation for the divergent findings in human studies of *Ureaplasma* and respiratory status in preterm infants. Premature baboon infants were delivered 48 to 72 hours after maternal intra-amniotic inoculation with *Ureaplasma*. Two distinct patterns of disease were observed in the baboon infants. Baboons with persistent *Ureaplasma* tracheal colonization manifested worse lung function and prolonged elevated tracheal cytokines. Conversely, colonized baboons that subsequently cleared *Ureaplasma* from tracheal cultures showed improved lung function compared with unexposed control animals.

In addition, pneumonia with persistent pulmonary hypertension has been described in newborn infants with *Ureaplasma* isolated from the lower respiratory tract [82,83]. Although cases of ureaplasmal pneumonia have been documented in full-term infants, pneumonia resulting from this agent is thought to occur much less frequently than in premature neonates. Case reports indicate that *M. hominis* can be a cause of pneumonia in newborns, but it has not been implicated as a common etiologic agent in prospective studies. These mycoplasmas are not thought to be a significant cause of acute respiratory disease in otherwise healthy infants after the first month of life [31].

## CHRONIC LUNG DISEASE

*Ureaplasma* frequently colonizes the neonatal respiratory tract. Although most investigations support a significant association between ureaplasmas and chronic lung disease (CLD) in preterm infants, its role in causation of CLD is uncertain. CLD is most often defined as a requirement for supplemental oxygen at 28 days of age or at 36 weeks of postconceptional age. Presence of concurrent chest radiographic changes compatible with CLD sometimes is included in this definition.

In a meta-analysis of 17 investigations published before 1995, Wang and coworkers [92] explored the association between *Ureaplasma* and CLD. The studies in this analysis included preterm and term neonates. CLD was defined as a requirement for oxygen at 28 to 30 days of age, and diagnosis of *Ureaplasma* colonization required the recovery of *Ureaplasma* from a respiratory or surface specimen. The estimates of relative risk exceeded 1 in all of the investigations; however, the lower confidence interval included 1 in 7 (41%). The meta-analysis concluded that the relative risk for the development of CLD in colonized infants was 1.72 (95% confidence interval 1.5 to 1.96) times that for noncolonized infants. In the analysis, investigations that focused on extremely premature, very low birth weight (VLBW) neonates did not identify a significantly different relative risk from that for investigations that included all neonates. Also, the relative risk

did not differ significantly between studies in which only endotracheal aspirates were used to define colonization and other studies.

Subsequent to this meta-analysis, the association of *Ureaplasma* with chronic pulmonary disease, including bronchopulmonary dysplasia (or CLD), has been confirmed in multiple studies [87,88,93–101], but not in others [102–108]. Perzigian and colleagues [94] prospectively investigated a cohort of 105 VLBW (<1500 g) infants; in 22 (21%) infants, results of tracheal aspirate cultures were positive for *Ureaplasma* at birth. At 28 days of age, *Ureaplasma*-positive patients were significantly more likely to have CLD than were *Ureaplasma*-negative patients, despite routine use of exogenous surfactant. *Ureaplasma*-positive infants also required significantly longer duration of oxygen therapy and of mechanical ventilation. No significant differences were found for CLD at 36 weeks of postconceptional age or for duration of hospitalization.

Another meta-analysis appraisal of the association between *Ureaplasma* and CLD was undertaken by Schelonka and coworkers [109] with investigations published before 2005. This analysis included 23 studies of infants colonized or infected with *Ureaplasma* with an aggregate of 2216 infants in whom CLD was defined as persisting oxygen requirement at 28 days of age and included 8 studies of 751 infants in whom CLD was defined at 36 weeks of postconceptional age. A significant association between respiratory *Ureaplasma* and CLD was shown at 28 days of age (odds ratio 2.8; 95% confidence interval 2.3 to 3.5) and 36 weeks of postconceptional age (odds ratio 1.6; 95% confidence interval 1.1 to 2.3).

Because neither the relationship of *Ureaplasma* species nor the concentration of ureaplasmas with the development of CLD had yet been investigated, a prospective study was designed to look for such an association. In 175 VLBW infants, endotracheal aspirates were obtained at birth for quantitative culture; the results were analyzed for correlation with the development of CLD [106]. Ureaplasmas were isolated from 66 (38%) of the 175 infants. No statistically significant associations were identified between the development of CLD and the *Ureaplasma* species isolated (*U. urealyticum* or *U. parvum*) or the concentration of ureaplasmas in the lower respiratory tract secretions.

Because the observed disparities in these studies might be explained in part by the variable persistence of *Ureaplasma* colonization of the infant respiratory tract, a prospective longitudinal study was performed to investigate this possibility. In 125 VLBW infants, culture and PCR assay were used to sample for *Ureaplasma* in the respiratory tract frequently over the course of their neonatal intensive care unit stay. It was found that the pattern of colonization was predictive for the development of CLD [95]. In this study, 40 (32%) of 125 infants had at least one specimen positive for *Ureaplasma*; however, only 18 (45%) of the 40 had persistent colonization throughout their hospitalization. Only persistent *Ureaplasma* colonization was associated with a significantly increased risk of development of CLD at 28 days of age and at 36 weeks after conception. Neither early transient colonization nor late acquisition of *Ureaplasma* was associated with CLD. The study by Yoder and colleagues [91] in premature baboons similarly found that the pattern of tracheal colonization was important in the manifestations of respiratory disease.

Inadequate detection of *Ureaplasma* in neonates can be another confounding factor in CLD research. False-negative results for isolation of *Ureaplasma* from respiratory specimens could weaken the calculated association with CLD. Using in situ hybridization for *Ureaplasma* on lung autopsy tissue from seven infants with positive cultures and seven infants with negative cultures for *Ureaplasma* from the lower respiratory tract, Benstein and coworkers [93] found all seven culture-positive infants were positive for *Ureaplasma* by in situ hybridization; two of the culture-negative infants were positive by in situ hybridization. The in situ hybridization results had 100% correlation with the presence of histopathologic evidence of bronchopulmonary dysplasia at autopsy of these 14 infants.

Although properly conducted antimicrobial agent trials showing reduction in CLD incidence and severity in neonates with *Ureaplasma* would support a causal role for this microorganism, failure of amelioration with effective therapy does not indicate that *Ureaplasma* does not have some role in the development of CLD. Small trials of therapy with erythromycin or clarithromycin have failed to provide evidence that therapy, predicted by in vitro testing to be effective, decreases CLD severity or produces clinical improvement in neonates with *Ureaplasma* [88,98,107,110–113]. Only two randomized, controlled trials have been conducted, together involving 37 VLBW infants with *Ureaplasma* isolated from the respiratory tract; each failed to show a reduction in the incidence of CLD after 7 to 10 days of erythromycin therapy [110]. In one of these trials, erythromycin treatment significantly reduced the isolation of *Ureaplasma* from the respiratory tract, but it did not significantly alter required length of time with supplemental oxygen [107]. A large, definitive, well-controlled trial is needed, perhaps with more prolonged antimicrobial therapy.

Debate over the concept that initiating therapy after birth may be too late to influence the outcome of an inflammatory process with possible onset in utero was partially addressed in the ORACLE (Overview of Role of Antibiotics in the Curtailment of Labour and Early Delivery) I and ORACLE II prenatal trials (erythromycin or amoxicillin-clavulanic acid or both in a randomized double-blind, placebo-controlled design) involving a combined total of 11,121 women with preterm, prelabor rupture of fetal membranes or spontaneous preterm labor [114,115]. One of the primary outcomes of these trials was CLD, defined as the need for daily supplementary oxygen at age 36 weeks after conception; the other primary outcomes were neonatal death and major cerebral abnormality. ORACLE I and ORACLE II revealed no statistically significant reduction in any primary outcome. *Ureaplasma* colonization was not specifically addressed in these trials, however, so the results should not be generalized to address *Ureaplasma* and CLD directly.

To investigate for the presence of a long-term detrimental effect of perinatal *Ureaplasma* infection, a cohort of 40 preterm infants was prospectively followed for

12 months [116]. In 22 (55%) infants, *Ureaplasma* was present in samples obtained from the trachea or blood or both at birth. Infants with perinatal *Ureaplasma* required significantly more days of hospitalization than infants without *Ureaplasma*. The difference was attributed to an increase in respiratory tract disease among the infants with perinatal *Ureaplasma*. In addition, CLD was associated with significantly more admissions in infants with perinatal *Ureaplasma* than in infants without it. Syrogiannopoulos and associates [75] monitored 108 full-term infants during the first 3 months of life. These researchers were unable to show an increased risk of lower respiratory illness during this period of observation in 51 of 108 infants with persistent pharyngeal *Ureaplasma* colonization compared with infants who were not pharyngeally colonized at 3 months of life.

Although *Ureaplasma* has not been definitively shown to cause CLD, investigations have identified possible pathogenic mechanisms through which it may contribute to CLD. *Ureaplasma* has been hypothesized to induce lung injury through immunopathogenic mechanisms involving the release of pulmonary cytokines and chemokines after exposure to this microorganism either in utero or postnatally. It also has been proposed that *Ureaplasma* infection potentiates oxygen-induced lung injury [93,95,117].

Although much effort has been expended to define the role of *Ureaplasma* in CLD, no clear conclusions can be made at the present time, although most of the investigations seem to indicate a significant association. Novel strategies need to be instituted to explore the link between these entities further.

## BLOODSTREAM INFECTIONS

Ureaplasmas have been isolated from blood cultures from neonates [45,73,74,81,118–121]. Case reports also have described the isolation of ureaplasmas from the bloodstream of neonates with pneumonia [72,83]. Cassell and associates [73] found that 26% of preterm infants with endotracheal aspirates that grew *Ureaplasma* also had a positive result on blood cultures for this organism, suggesting that bacteremia with ureaplasmas can be common in preterm infants. Cases of *M. hominis* bacteremia with systemic symptoms accompanied by an antibody response also have been reported [122,123].

Not all investigations have been successful in recovering mycoplasmas from the blood of infants [118,124,125]. Mycoplasmas were not isolated from blood cultures obtained within 30 minutes of birth from 146 preterm infants in Israel [118]. In addition, investigators did not isolate mycoplasmas from the 191 blood cultures in a prospective study of older infants hospitalized for possible sepsis [125].

Goldenberg and coworkers [126] evaluated the frequency of umbilical cord blood infections with *Ureaplasma* and *M. hominis* in 351 mother-infant pairs with deliveries between 23 and 32 weeks' gestational age to determine their association with various obstetric conditions, markers of placental inflammation, and newborn outcomes. *Ureaplasma* or *M. hominis* or both were present in 82 (23%) cord blood cultures. Of the women with a positive cord blood culture for *Ureaplasma* or *M. hominis* or both, 43 (52%) had *Ureaplasma* only, 21 (26%) had *M. hominis* only, and 18 (22%) had *Ureaplasma* and *M. hominis*. Positive cultures for *Ureaplasma* or *M. hominis* or both were more common in infants of nonwhite women (27.9% versus 16.8%; $P = .016$), in women younger than 20 years of age, in women undergoing a spontaneous compared with an indicated preterm delivery (34.7% versus 3.2%; $P = .0001$), and in women delivering at earlier gestational ages. Intrauterine infection and inflammation were more common among infants with a positive cord blood culture for *Ureaplasma* or *M. hominis* or both, as evidenced by positive placental cultures for these and other bacteria, elevated cord blood interleukin-6 levels, and placental histology. Infants with positive cord blood cultures for *Ureaplasma* or *M. hominis* or both were more likely to have neonatal systemic inflammatory response syndrome (41.3% versus 25.7%; adjusted odds ratio 1.86; 95% confidence interval 1.08 to 3.21), but were not significantly different for other neonatal outcomes, including CLD (26.8% versus 10.1%; adjusted odds ratio 1.99; 95% confidence interval 0.91 to 4.37), respiratory distress syndrome, intraventricular hemorrhage, or death.

## CENTRAL NERVOUS SYSTEM INFECTIONS

Generally, the clinical significance of recovering *Ureaplasma* or *M. hominis* from a central nervous system (CNS) specimen from a neonate is uncertain. In some situations, an association with a disease process seems plausible, whereas in others, no corresponding disease state is apparent. Multiple cases of *M. hominis* CNS infection (meningitis, brain abscess) have been described in full-term and preterm infants [127–137]. *Ureaplasma* also has been isolated from the CSF of infants with suspected sepsis and meningitis [3,72,81,124,138–140].

In a prospective trial in 100 mostly premature infants, *Ureaplasma* was isolated from the CSF of 8 and *M. hominis* was isolated from the CSF of 5 who were undergoing investigation for suspected sepsis or treatment of hydrocephalus [81]. Of the eight neonates with *Ureaplasma*, six had severe intraventricular hemorrhage, three had hydrocephalus, and four had ureaplasmas isolated several times in the CSF. *Ureaplasma* infection was significantly associated with severe intraventricular hemorrhage ($P < .001$). *Ureaplasma* was isolated from the respiratory tract of four of the eight infants with CSF infections. Five infants received treatment with erythromycin or doxycycline. Three infants with *Ureaplasma* infection died. All five of the neonates from whom *M. hominis* was isolated from the CSF were being investigated for suspected sepsis; prominent neurologic signs and CSF pleocytosis were noted in only one neonate. This infant received doxycycline treatment and improved, but had substantial neurologic sequelae (Fig. 20–2) [81]. No infants infected with *M. hominis* died. A subsequent study by the same group of investigators in 318 infants isolated *Ureaplasma* from the CSF of 5 and *M. hominis* from the CSF of 9. Spontaneous clearance of the organisms was documented in 5 of the infants, and 12 infants had a good outcome [141].

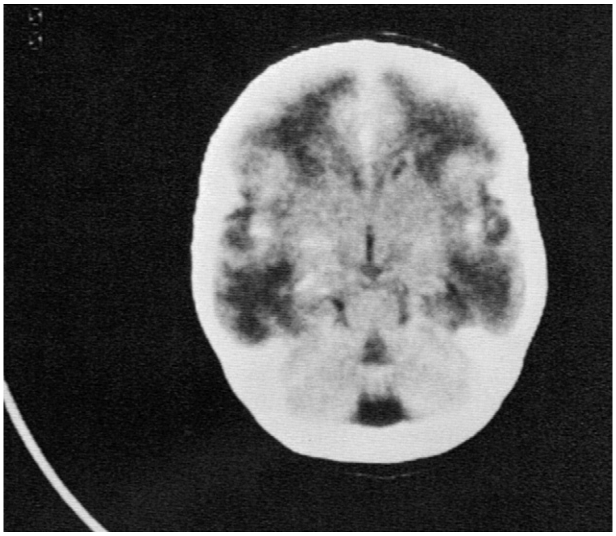

**FIGURE 20–2** **A 37-week gestation newborn who had hypothermia, hypotonia, and lethargy noted at age 3 days.** Computed tomography (CT) showed decreased attenuation predominantly of supratentorial white matter symmetrically with punctate early calcified lesions. Examination of cerebrospinal fluid showed mononuclear pleocytosis, and *Mycoplasma hominis* was isolated. Cerebrospinal fluid culture was sterile after 5 days of doxycycline treatment, but the infant had spastic quadriplegia at 6 months of age.

Shaw and colleagues [142] performed a prospective study of 135 preterm infants undergoing lumbar puncture and found *Ureaplasma* in the CSF of 1 neonate and *M. hominis* in none. *Ureaplasma* continued to be isolated from this one infant over the course of 16 weeks, despite treatment with erythromycin. The organism maintained in vitro susceptibility to erythromycin. Doxycycline treatment was associated with the disappearance of the organism.

In a prospective study by Ollikainen and coworkers [72], *Ureaplasma* was isolated from the CSF of four of six infants born at less than 34 weeks of gestation. None had pleocytosis or hypoglycorrhachia in the CSF. Three had the organism also isolated from blood, and one had *Ureaplasma* isolated from a tracheal sample. One infant died and had a postmortem brain culture positive for *Ureaplasma*. None had intracranial hemorrhage.

Valencia and associates [124] isolated *M. hominis* from 9 and *Ureaplasma* from 1 of 69 consecutive infants in whom CSF was cultured within the first 3 months of life for suspected sepsis. The CSF indices except for bloody specimens were considered to be normal for newborns. Only one of the infants whose CSF culture grew *M. hominis* had clinical signs compatible with systemic infection. The other infants were healthy, but were evaluated secondary to maternal fever and prolonged rupture of membranes. All 10 infants received ampicillin and gentamicin, antimicrobial agents without good activity against these organisms, and had a good clinical outcome.

In cultures of CSF from 920 infants in a neonatal intensive care unit, *Ureaplasma* was isolated from 2 (0.2%), and *M. hominis* was isolated from none [111]. Likitnukul and colleagues [125] and Mardh [127] failed to recover mycoplasmas from CSF of infants in prospective investigations. The study by Likitnukul's group [125] involved infants who had been previously discharged from the hospital and had returned because of suspected sepsis. No mycoplasmas were recovered from the CSF of 47 preterm infants cultured within the 1st week of life by Izraeli and coworkers [118]. The reason for the frequent isolation of mycoplasmas in some studies but not in others is uncertain. Possible technical reasons are discussed by Waites and colleagues [143] and Heggie and associates [144].

The question of whether mycoplasmas are linked to abnormalities on CNS imaging also has been investigated, although in an indirect manner. Perzigian and associates [94] prospectively investigated a cohort of 105 VLBW infants in whom 22 (21%) results of tracheal aspirate culture were positive for *Ureaplasma* at birth. No differences were found between the groups for intraventricular hemorrhage or cystic periventricular leukomalacia. Similarly, in a study of 464 VLBW infants, Dammann and coworkers [145] addressed the question of whether *Ureaplasma* or *M. hominis* cultured from the placenta was associated with an increased risk of cerebral white matter echolucency on ultrasonography as a measure of white matter damage. The cranial ultrasound studies were performed up to a median of 22 days of life. Culture results were as follows: 139 of 464 (30%) were positive for *Ureaplasma*, 27 (6%) were positive for *M. hominis*, and 21 (5%) were positive for *Ureaplasma* and *M. hominis*. It was found that with a positive result on culture for *Ureaplasma*, the infants were not at increased risk of cerebral white matter damage. The presence of *M. hominis* was associated with a trend toward an increased risk of echolucency ($P = .08$).

The clinical findings in newborns with *Ureaplasma* and *M. hominis* isolated from the CSF are variable. *Ureaplasma* and *M. hominis* may produce abnormal CSF indices with pleocytosis, or an inflammatory reaction in CSF may be absent [72,81,124,127]. In some infants, mycoplasmas are cleared spontaneously from the CSF, whereas in others, the organisms have been shown to persist for weeks to months even after appropriate treatment [31,134,146–148].

## OTHER SITES OF INFECTION IN THE NEONATE

*M. hominis* also has been isolated from pericardial fluid [149], subcutaneous abscesses [150–152], and the submandibular lymph node of neonates [153]. The first reported case of *M. hominis* endocarditis in a child was published more recently [154]. *Ureaplasma* and *M. hominis* have been isolated from the urine, but the clinical significance was uncertain [125].

## OTHER MYCOPLASMAS

The role of other mycoplasmas, such as *M. genitalium*, *M. fermentans*, and *M. pneumoniae*, in maternal and fetal and neonatal infections is not thought to be prominent, although investigations are limited. *M. genitalium* was not isolated by culture of the chorioamnion of 609 women or by culture or PCR assay of 232 amniotic fluid samples tested [155]. To evaluate the impact of

*M. genitalium* on the outcome of pregnancy, cervical samples from 1014 women were assayed by PCR techniques for the presence of *M. genitalium* [156]. Among those women, *M. genitalium* was isolated in 6.2%, but its isolation was not significantly associated with adverse outcomes of pregnancy (preterm delivery, small for gestational age, spontaneous abortion, stillbirth). Taylor-Robinson [157] more recently reviewed disease associations with *M. genitalium*.

*M. fermentans* was detected in amniotic fluid collected at the time of cesarean section from 4 of 232 women with intact membranes [155]. Placental tissue also was positive for *M. fermentans* on PCR assay in three women. Villitis and chorioamnionitis were present in two of the four positive specimens, and no other organisms were detected.

## DIAGNOSIS

Culture and PCR assay are appropriate methods for the diagnosis of *Mycoplasma* and *Ureaplasma* infections. Culture of *Ureaplasma* and *M. hominis* requires special handling, however, with techniques and media generally unavailable outside major medical centers or reference laboratories. Detailed laboratory techniques for culture and identification of mycoplasmas and ureaplasmas have been reviewed by others [31,158].

Ureaplasmas and mycoplasmas are extremely susceptible to adverse environmental conditions. Correct methods of collecting, processing, and transporting specimens are important for reliable and interpretable culture results. A specific ureaplasmal transport medium, such as Shepard's 10B broth [159,160], for *Ureaplasma* and *M. hominis* should be available for direct inoculation of clinical specimens and swabs at the time of collection. If specimens are allowed to sit at room temperature and are not inoculated into appropriate media, the recovery of these organisms is unlikely. Only swabs tipped with calcium alginate or Dacron with plastic or wire shafts should be used for sampling of mucosal surfaces. Blood should be collected free of anticoagulants and immediately inoculated into the transport medium in a 1:5 to 1:10 ratio [31].

Specimens should be refrigerated at 4° C and protected from drying in a sealed container until transported to the laboratory. If transport to a suitable laboratory is not possible within 6 to 12 hours after collection, the specimen in appropriate transport medium should be stored at −70° C and shipped frozen on dry ice. Ureaplasmas and mycoplasmas are stable for long periods when kept frozen at −70° C in a protein-containing support medium such as Shepard's 10B broth. Storage at −20° C is less reliable and results in a significant loss in number of organisms in a relatively short time [31]. Before collecting a clinical sample for culture, it is appropriate to arrange processing of samples with the microbiology laboratory.

*Ureaplasma* and *M. hominis* grow within 2 to 5 days. Broth cultures are incubated at 37° C under atmospheric conditions; agar plates are incubated under 95% nitrogen and 5% carbon dioxide. Colonies of *Ureaplasma* can be identified on A8 agar by urease production. The colonies often are amorphous. Colonies of other mycoplasmas are urease-negative and have a typical "fried egg" appearance (Fig. 20–3).

PCR assays for the detection of *Ureaplasma* and *M. hominis* [104,161–163] have been developed. These

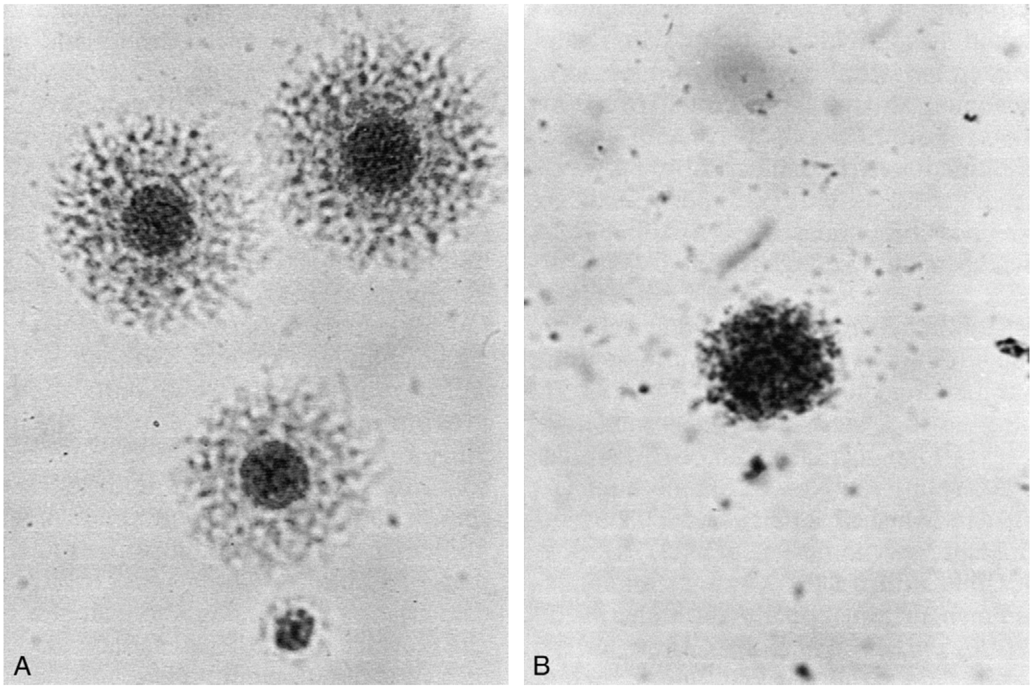

**FIGURE 20–3** **A,** *Mycoplasma hominis*. (Original magnification 100×.) **B,** *Ureaplasma*. (Original magnification 1000×.) *(Adapted from Klein JO. Mycoplasmas, genitourinary tract infection, and reproductive failure. Hosp Pract 6:127-133, 1971.)*

assays seem to have greater sensitivity than culture in most studies [35,36,95,164,165]. A combination of PCR assay and culture should give the most reliable results. Although enzyme-linked immunosorbent assays have been developed to detect *Ureaplasma*-specific and *M. hominis*–specific antibodies in sera, serologic testing is not recommended for the routine diagnosis of *Ureaplasma* and *M. hominis* infections. The use of these assays is limited to the research setting. Owing to the fastidiousness and slow growth of *M. genitalium* and *M. fermentans*, PCR assay, in situ hybridization, and immunohistochemistry are recommended for detection of these mycoplasmas [155,166,167].

## TREATMENT OF NEONATAL INFECTIONS

A positive result on culture or PCR assay for *Ureaplasma* or *M. hominis* from a normally sterile site, particularly in the absence of other microorganisms, is justification to consider treatment for infants with evidence of infectious inflammation. On the basis of the current understanding of these organisms, however, the isolation of *Ureaplasma* or *M. hominis* in the absence of disease generally does not warrant treatment.

Formulation of guidelines for treatment when these organisms are isolated from a maternal or fetal or neonatal specimen is difficult, in view of the following considerations as reviewed in this chapter:

- Causation has not been clearly established for many conditions associated with *Ureaplasma* and *M. hominis* (all maternal and fetal and neonatal associations except postpartum and postabortal fever).
- Organisms often are present (e.g., in CSF, bloodstream, respiratory tract, amniotic fluid, or lower genital tract) with little or no adverse clinical outcome.
- Organisms often are spontaneously cleared (e.g., from CSF, bloodstream, or respiratory tract) without treatment.
- No definitive controlled trials have been performed for many sites of infection (e.g., CSF, bloodstream, amniotic fluid, lung in acute pneumonia).
- Small randomized, controlled trials have not shown benefit of treatment for CLD.
- Evidence that treatment can be useful comes from uncontrolled case reports for which the outcome without treatment is unknown.
- Comparative clinical trials among antimicrobials have not been performed to assess their relative efficacy.
- Often the clinical indication for culture or PCR assay has resolved before the positive result is reported.

Treatment may be warranted in some situations, so decisions must be made on a case-by-case basis, to ensure full consideration of the risk-benefit ratio related to disease and treatment. The relative contribution of *Ureaplasma* and *M. hominis* infection to morbidity and mortality is difficult to establish because most cases have been reported in VLBW preterm infants with multiple complications or in infants with clinical problems that probably contribute to the poor outcome. An authoritative reference states that antimicrobial therapy for *Ureaplasma* cannot be recommended for pregnant women to prevent preterm delivery or for preterm infants to prevent pulmonary disease because trials of antimicrobial therapy for these indications generally have not shown efficacy [168]. It also suggests that definitive efficacy of antimicrobial agents in the treatment of CNS *Ureaplasma* infections in infants is lacking [168].

The treatment of some non-neonatal *Ureaplasma* and *M. hominis* infections is better established. *Ureaplasma* urethritis and *M. hominis* pyelonephritis, pelvic inflammatory disease, postabortal fever, and postpartum fever and infections with either organism in immunocompromised patients (especially patients with hypogammaglobulinemia) generally are considered to warrant treatment.

Erythromycin generally has been considered the antimicrobial agent of choice for neonatal ureaplasmal infections (not involving the CNS), although clinical superiority over other agents has not been investigated [169]. Erythromycin has been employed in most clinical trials in infants with *Ureaplasma* [98,107,110–113]. Other agents with in vitro activity against *Ureaplasma* and variable clinical experience include clarithromycin, azithromycin, doxycycline, and chloramphenicol [88,170–173]. In vitro activities of newer agents, such as quinolones and ketolides, against *Ureaplasma* have been reported; clinical experience is largely lacking [169,174–177]. Resistance to macrolides, doxycycline, fluoroquinolones, and chloramphenicol has been reported [169,178–180]. *M. hominis* is resistant to erythromycin and to other macrolides and azolides [169–172]. Doxycycline is the drug of choice for treatment of *M. hominis* infections, although resistance has been reported [13,134,181–183]. Clindamycin and chloramphenicol also are generally active in vitro against *M. hominis* [169]. In vitro activity of newer antimicrobials against *M. hominis* has been reported; clinical experience is lacking, however [169,174–177].

Antimicrobial susceptibility testing should be considered when it is deemed necessary to treat *Ureaplasma* or *M. hominis* infection in a neonate, especially for the persistent isolation of either organism from a normally sterile site, because resistance to commonly used antibiotics is not rare. Some tetracycline-resistant strains of *Ureaplasma* can be erythromycin resistant, but high-level erythromycin resistance in *Ureaplasma* is uncommon [164]. Penetration of the blood-brain barrier by antimicrobials should be considered in treating a CNS infection, as should the safety and pharmacokinetics of antimicrobials in newborns in making treatment decisions.

CHAPTER 21

# Human Immunodeficiency Virus/Acquired Immunodeficiency Syndrome in the Infant

**Avinash K. Shetty** · **Yvonne A. Maldonado**

## CHAPTER OUTLINE

Since the first descriptions of acquired immunodeficiency syndrome (AIDS) in infants and children in the early 1980s [1–4] the epidemiology of pediatric human immunodeficiency virus (HIV) infection has changed significantly in the United States [5–7]. Perinatal transmission is the most common source of HIV infection among infants and children [8]. Although HIV infection in children has been acquired in the past by the transfusion of contaminated blood or coagulation products, this route has been virtually eliminated in the United States. Remarkable progress has been made in prevention of perinatal transmission of HIV during the last decade in developed nations [9]. Dramatic declines in the number of HIV-infected children who acquired the infection perinatally have been reported in the United States because of prompt implementation of effective, cost-saving strategies to prevent mother-to-child transmission of HIV [10–13].

Rates of perinatal HIV transmission in the United States and Europe have decreased to 2% or less because of widespread implementation of universal antenatal HIV testing, combination antiretroviral treatment during pregnancy, elective cesarean section, and avoidance of breast-feeding [14–17]. Currently, less than 200 infants acquire HIV from their mothers in the United States annually primarily because of missed prevention opportunities [18]. Availability of highly active antiretroviral therapy (HAART) has led to improved survival of HIV-infected children into adolescence and adulthood changing most HIV infections into a treatable chronic disease rather than a fatal disease [19–25].

In contrast, prevention of mother-to-child transmission of HIV is a major public health challenge in resource-limited nations [9,26]. More than 90% of these affected children reside in sub-Saharan Africa [27]. Although several effective, simple, and less expensive prophylactic antiretroviral regimens are available to prevent perinatal HIV transmission, less than 10% of HIV-infected pregnant women have access to these preventive interventions in the developing world [28]. In addition, progress has been slow in scaling-up HAART in sub-Saharan Africa; only 23% of HIV-infected individuals who need HAART are receiving it [28], and only 5% to 7% of the individuals receiving treatment are children [29,30]. This chapter reviews advances in the prevention of perinatal HIV transmission; discusses evaluation and management of HIV-exposed infants in the United States; and highlights certain unique features of HIV infection in infants, with a focus on early diagnosis, clinical manifestations, treatment, and prognosis.

## EPIDEMIOLOGY

HIV infection is a pandemic with cases reported to the World Health Organization (WHO) from virtually every country. At the end of December 2007, an estimated 33 million people were living with HIV, including 13 million women of childbearing age and 2.5 million children younger than 15 years [28]. Resource-limited settings bear the brunt of the epidemic with 22.5 million HIV-infected people living in sub-Saharan Africa [28]. It has been estimated that in 2007, 420,000 children were newly infected with HIV [28], primarily through mother-to-child transmission of HIV; 70% of infants were born in sub-Saharan Africa, 25% in Southeast Asia, and the remainder in Latin America and the Carribean [28]. In 2007, 330,000 children younger than 15 years died of HIV-related complications [28]. In developing nations, children constitute 14% of new HIV infections worldwide and nearly one fifth of annual HIV deaths [28].

Primary HIV infection among women of childbearing age fuels the perinatal HIV epidemic. In some countries in sub-Saharan Africa, antenatal HIV prevalence can reach 40% [28]. Approximately 3.28 million pregnant women infected with HIV give birth annually primarily in resource-limited settings, where approximately 1800 HIV-infected infants are born each day. More than 50% of HIV-infected children in sub-Saharan Africa die by 2 years of age [31]. The Joint United Nations Program on HIV/AIDS (UNAIDS) estimates that 15 million children have been orphaned by the AIDS epidemic [28].

The average HIV seroprevalence among women in the United States has been estimated at 1.5 to 1.7 in 1000 women of childbearing age [32]. Characteristics of the HIV epidemic among women of reproductive age affect the pediatric HIV epidemic [32]. Regional HIV seroprevalence rates vary, with the highest rates found among women residing in the Northeast and in the South, especially in New York, Florida, Texas, and New Jersey [32]. Based on these rates, it is estimated that around 6000 to 7000 HIV-infected women give birth in the United States each year [32,33]. Of the estimated 123,405 women and adolescent girls living with HIV/AIDS at the end of 2004, 71% contracted infection through heterosexual contact, and 27% had been exposed through injection drug use [34]. Although the association of intravenous drug use as a risk factor for HIV infection among women has been relatively constant, HIV-infected women with heterosexual contact as the only risk factor for HIV infection increased from 14% in 1982 to 40% of all HIV-infected women in 2000 [35]. Heterosexual transmission of HIV to women of childbearing age is likely to continue to account for most perinatal HIV infection in the United States.

The rate of HIV infection among women of childbearing age has continued to increase. Of reported AIDS cases in adults, women accounted for 7% in 1985, 13% in 1993, and 23% in 1999 [33]. In 2004, 27% of 44,615 reported AIDS cases among adults and adolescents were in women and adolescent girls [34]. African American and Hispanic women are disproportionately affected by the HIV epidemic. More than 75% of women with AIDS are in the reproductive age group at the time of diagnosis. Despite improved survival because of effective HAART regimens, transmission is ongoing, and young women are at highest risk [36].

Adolescents represent a growing population of HIV infection, with at least 5000 individuals 13 to 19 years old living with HIV. Many HIV-infected adolescents acquired their infection perinatally. In the United States, HIV-infected children younger than 13 years account for only 1% of all AIDS cases [37]. Since the beginning of the epidemic, 9441 cases of AIDS in children younger than 13 years have been reported in the United States [36]. Perinatal transmission is the most common source of pediatric HIV infection, accounting for 91% of cases; 4% acquired infection through receipt of blood or blood products, and another 2% acquired HIV-1 from transfusion because of hemophilia. Approximately 2% of cases have been reported to have no identifiable risk factor [36,38]. The number of infants born with HIV-1 has decreased from a high of 2000 per year in the early 1990s to less than 150 [10]. At the same time, new pediatric AIDS cases and AIDS deaths also have dramatically declined, primarily because of availability of HAART.

In 2005, 93 AIDS cases were reported in children younger than 13 years compared with 122 cases in 2004 and 858 cases in 1992. New York and Florida reported the highest number of cases. The racial and ethnic and geographic distribution of AIDS cases in children parallels that of women with AIDS. Minority groups are disproportionately affected, with 59% of cases occurring among African American, non-Hispanic children (who account for only 14% of the U.S. pediatric population) and 23% occurring in Hispanics (17% of the U.S. pediatric population) compared with 17% occurring in white, non-Hispanic children (64% of the U.S. pediatric population) [36].

## TRANSMISSION

Mother-to-child transmission of HIV-1 can occur in utero, during labor and delivery, or postnatally through breast-feeding [6–8] Data suggest that most children are infected during the immediate peripartum period [6]. In the United States, the transmission rate without intervention is estimated to be 25% to 30%; in Europe, it is lower at 15% to 20%. A transmission rate of 25% to 45% has been observed among breast-feeding populations in Africa [39,40]. These variations in transmission rates likely reflect differences in infant feeding patterns, maternal and obstetric risk factors, viral factors, and methodologic differences among studies. Maternal disease status, especially a high viral load or a $CD4^+$ count less than 200 cells/$mm^3$, is highly correlated, however, with the risk for vertical transmission [39,41–45]

Knowledge about the precise timing of transmission is crucial for the design of potential preventive strategies [46]. In non–breast-fed infants, about one third of transmissions occur during late gestation, and the remaining two thirds occur during delivery [47]. In breast-fed infants, one third to one half of overall transmission may occur after delivery during lactation [48,49].

### INTRAUTERINE TRANSMISSION

In utero transmission may occur through HIV infection in the placenta or fetal exposure to cell-free or cell-associated HIV in the amniotic fluid. Virus has been

detected in some aborted fetuses of 8 to 20 weeks' gestational age and in amniotic fluid [50–53]. Maternal decidual leukocytes, villous macrophages (Hofbauer cells), and endothelial cells stain positive for gp41 antigen and HIV nucleic acids [54]. The placenta can be infected through CD4$^+$ trophoblasts or through the occasional occurrence of chorioamnionitis [55,56]. There is not a clear predictive value for the identification of HIV in the placenta and the infection of the fetus or newborn [57]. There are important technical limitations to studies of fetal or placenta tissues, particularly because of the difficulty in excluding contamination with maternal blood.

## INTRAPARTUM INFECTION

Intrapartum transmission may occur in various ways, including direct exposure of the fetus or infant with infected maternal secretions during birth, ascending infection after rupture of membranes, or maternal-to-fetal microtransfusions during uterine contractions [58]. The bimodal course of disease in HIV-infected children and the fact that at the time of birth virus can be recovered from less than 25% of the infants who are subsequently shown to be infected suggest that a large proportion of perinatal infections occur late during pregnancy or during delivery [58]. An infant is considered to have been infected in utero if the HIV-1 genome can be detected by polymerase chain reaction (PCR) or be cultured from blood within 48 hours of birth [59].

In contrast, an infant is considered to have intrapartum infection if diagnostic assays such as culture, PCR, and serum p24 antigen were negative in blood samples obtained during the first week of life, but became positive during the period from day 7 to day 90, and the infant had not been breast-fed [59]. Intrapartum transmission is supported by studies failing to detect HIV in infants born to HIV-infected women in the first month of life but with subsequent detection of virus after 1 to 3 months of life [60–64]. In a study by the French Collaborative Study Group, timing of transmission was estimated with a mathematical model [65]. Data for the 95 infected infants (infants seropositive at 18 months and infants who died of HIV disease before this age and who were exclusively bottle-fed) were used in the model, which indicated that one third of the infants were infected in utero less than 2 months before delivery (95th percentile). In the remaining 65% of cases (95% confidence interval [CI] 22% to 92%), the date of infection was estimated as the day of birth. The estimated median period between birth and the positivity of viral markers (HIV PCR or HIV culture) was 10 days (95% CI 6% to 14%), and the 95th percentile was estimated at 56 days [65].

Discordance of infection has been described among the progeny of different pregnancies and even among twins [66–69] Retrospective studies of twins born to HIV-infected women found a higher HIV transmission rate among twins born by vaginal delivery compared with twins born by cesarean delivery and among first-born compared with second-born twins. In a large multinational study, data were collected on 100 sets of twins and one set of triplets born to HIV-seropositive mothers [68]. HIV-1 infection was more common in first-born than in second-born twins ($P = .004$), with 50% of first-born twins delivered vaginally and 38% of first-born twins delivered by cesarean section being infected compared with 19% of second-born twins delivered by either route. These data support exposure to maternal virus during delivery as a likely route of transmission.

Although numerous maternal, obstetric, infant, and viral factors may modify perinatal HIV transmission risk [70,71], the strongest predictor of intrauterine and intrapartum transmission is the maternal serum HIV RNA level [43,72–79]. Transmission can occur rarely, however, among pregnant women with low or undetectable serum levels of HIV around the time of labor and delivery [41].

Other maternal risk factors associated with higher rates of perinatal HIV infection include women with progressive symptoms of AIDS, acute HIV infection during pregnancy, and low CD4$^+$ counts [80–84]. HIV viral load in cervicovaginal secretions is an independent risk factor for perinatal HIV transmission [85]. Obstetric risk factors associated with increased risk of transmission include vaginal delivery, rupture of membranes for more than 4 hours, chorioamnionitis, and invasive obstetric procedures [84,86,87]. Premature infants born to HIV-infected women have a higher rate of perinatal HIV infection than full-term infants [88–90] Data from a large international meta-analysis of 15 prospective cohort studies and a randomized controlled trial from Europe have shown that cesarean section performed before labor and rupture of membranes reduces perinatal transmission of HIV-1 by 50% to 87% independent of the use of antiretroviral therapy or zidovudine prophylaxis [91,92]. Other risk factors reported include viral subtype and host genetic factors [6,47]. High viral heterogeneity in the mother is a risk factor for vertical transmission [93,94]. Increased transmission of HIV strains that are fetotropic is reported; isolation of HIV strains with highly conserved gene sequences from HIV-infected infants has been shown, despite the numerous genetically diverse strains isolated from their mothers [93]. Maternal-fetal HLA concordance and maternal HLA homozygosity increase the risk of perinatal transmission [94], whereas CCR5 haplotype may be permissive or protective, depending on the specific mutation [95].

## POSTPARTUM INFECTION

In resource-poor settings, where breast-feeding is the cultural norm and safe replacement feeding is not affordable, feasible, sustainable, or safe, postnatal transmission of HIV through breast milk remains a significant challenge [48,49]. Transmission of HIV through breast-feeding can account for one third to one half of all HIV infections globally and carries an estimated transmission risk of about 15% when prolonged and continued into the 2nd year of life [48,49,96–100]. HIV has been isolated from cellular and cell-free fractions of human breast milk from HIV-infected women [101,102]. HIV has been shown by culture or PCR in varying frequencies (39% to 89%) in breast milk specimens from HIV-seropositive women [103–105]. More recent studies indicate that cell-associated virus is a stronger predictor for transmission of HIV to the infant than cell-free virus [106,107].

More recent data also indicate that HAART administered during pregnancy or postpartum suppresses HIV RNA, but not HIV DNA, in breast milk [108].

A meta-analysis estimated the overall additional risk of breast milk transmission as 14% (95% CI 7% to 22%) for established maternal infection to 29% (95% CI 16% to 42%) for primary infection [109]. Some studies show that the highest risk of breast milk HIV transmission occurs during the first few months of life, with a lower but continued risk thereafter [98,110]. In a randomized controlled trial of breast-feeding versus formula-feeding on HIV-1 transmission in Kenya, investigators found that formula-feeding reduced transmission by 44% at age 2 years and that 75% of infections were acquired during the first 6 months of life [110]. Studies from Malawi report a risk of 0.6% to 0.7% per month in the 1st year of life from 1 month through 12 months and 0.3% per month in the 2nd year of breast-feeding [98,111].

In an international multicenter pooled meta-analysis of greater than 900 mother-infant pairs, the risk of late postnatal transmission (>4 months of age) was 3.2 cases (CI 3.1 to 3.8) per year per 100 breast-fed infants [112]. Data from a more recent meta-analysis suggest that the risk of postnatal HIV transmission is constant (approximately 0.9% per month) between 1 and 18 months of age [113]. Risk factors for breast milk HIV transmission include women seroconverting during lactation, high HIV DNA or RNA level in plasma and breast milk, decreased maternal $CD4^+$ cell count, maternal symptomatic disease or AIDS, prolonged breast-feeding, mixed infant feeding, thrush and other infant coinfections, bleeding or cracked nipples, subclinical and clinical mastitis, and breast abscesses [48,49,96,114–117].

Several large studies have shown a lack of transmission of HIV infection to household contacts through casual interactions [118–121]. The American Academy of Pediatrics (AAP) does not place any special restrictions on day care or school attendance of HIV-infected children, but recommends observance of universal precaution measures for all handling of blood and body fluids, regardless of the infection status of the child [122,123]. The same guidelines apply to the handling of all newborns during or after birth. Gloves should be worn when handling body fluids, including amniotic fluid, and only bulb or wall suction devices should be used to avoid exposure of medical personnel [124].

## MOLECULAR BIOLOGY

HIV-1 is an enveloped virus with a diameter of approximately 110 nm and a cylindrical, electrodense core. HIV-1 and its close relative HIV-2 are members of the Lentiviridae family of retroviruses, which have a complex genomic structure [125,126]. HIV-1 variants are classified into three major groups: group M (main), group O (outlier), and group N (non-M/non-O). Group M accounts for most HIV-1 infections globally and is divided further into 10 subtypes or clades (A to K). Individuals who acquire HIV-1 infection in the United States, Western Europe, and Australia are most frequently infected with subtype B [125,126]. Other HIV-1 subtypes circulate globally. Subtypes C and D predominate in southern and eastern Africa, subtype C predominates on the Indian subcontinent, and subtype E is common in Southeast Asia [125,126].

Similar to all retroviruses, HIV-1 contains the genes for *gag*, which encodes the core nucleocapsid polypeptides (gp24, p17, p9); *env*, which encodes for the surface-coated proteins of the virus (gp120 and gp41), and *pol*, which encodes for the viral reverse transcriptase and other enzymatic activities (i.e., integrase and protease). There are two regulatory (*tat* and *rev*) and four accessory proteins (*vif*, *vpr*, *vpu*, and *nef*) that are essential for viral replication and pathogenicity [127]. The retroviral core also contains two copies of the viral single-stranded RNA associated with enzymes such as the reverse transcriptase, RNase H, integrase, and protease [128].

The life cycle of HIV-1 is characterized by several distinct stages [128]. The first step in the entry process of HIV into a cell is the binding of the virion envelope glycoproteins (gp120 and gp41) to CD4 on resting or activated T cells. This binding results in conformational change in the envelope, interaction with a coreceptor, and fusion of the viral and cell membranes, allowing the viral genome to gain entry into the cell [129–135]. Members of the chemokine receptor family are coreceptors for HIV. Human cord blood mononuclear cells are preferentially infected by macrophage-tropic (M-tropic) strains of HIV-1 using the CC chemokine receptor CCR5 [133,135,136]. T cell–tropic strains replicate in $CD4^+$ T cells and macrophages. They use the chemokine receptor CXCR4, a member of the CXC chemokine family [129,132,133,135].

HIV virions enter the cell and are rapidly uncoated. The viral reverse transcriptase transforms the single-stranded viral RNA into linear double-stranded DNA, whereas the less specific ribonuclease H degrades and removes the RNA template [137]. This viral DNA is circularized and transferred to the nucleus, where it is inserted by the viral integrase at random sites as a provirus [138,139]. It is also a common feature of all retroviruses to accumulate large amounts of unintegrated viral DNA that are fully competent templates for HIV-1 core and envelope antigen production [140]. The inactive provirus in the form of HIV-1 DNA has been found in 0.1% to 13.5% of peripheral blood mononuclear cells compared with viral mRNA, which is found in 0.002% to 0.25% of these cells [141–143]. The latent provirus is activated by host cell responses to antigens, mitogens, cytokines such as tumor necrosis factor, and different gene products of other viruses [143–146].

HIV gene expression follows by using host cell RNA polymerase II (among other factors), forming a ribonucleoprotein core containing *gag* and *pol* gene products. The 53-kDa precursor of the *gag* protein is cleaved by the HIV-1–derived protease into p24, p17, p9, and p7 proteins [147–149]. The assembly of new virions consists of the formation of the critical viral enzymes, including reverse transcriptase, integrase, ribonuclease, and a protease, and the aggregation into a ribonucleoprotein core [150,151]. The core subsequently moves to the cell surface and buds as mature virions through the plasma membrane.

The exact molecular mechanisms of vertical transmission are unclear, but studies analyzing the *env* gene have shown that the minor genotypes of HIV-1 with macrophage tropic and non–syncytium-inducing phenotypes (R5 viruses) are transmitted from mother to infant [152–155]. Studies have shown that HIV-1 replicates more efficiently in neonatal (cord blood) cells compared with adult cells because of increased HIV-1 gene expression [156], resulting in high viral load and rapid disease progression [157,158]. Analysis of many HIV-1 regulatory and accessory genes, including *vif*, *vpr*, *vpu*, *nef*, *tat*, and *rev*, has revealed conservation of functional domains of these genes during vertical transmission [159,160]. In addition, the *vif* and *vpr* sequences of transmitting mothers were more heterogeneous and more functional than sequences of nontransmitting mothers [153,160]. Other HIV-1 genes may also play a crucial role in virus transmission and pathogenesis. A more recent study showed that functional domains in the HIV-1 functional long terminal repeat (LTR) were conserved during vertical transmission, suggesting that a functional LTR sequence is crucial in viral gene expression, transmission, and pathogenesis [161].

## PATHOGENESIS OF EARLY INFANT INFECTION

### VIRAL PATHOGENESIS

Research conducted over the past 2 decades has yielded significant insights into understanding of the viral and immunopathogenesis of vertical HIV infection [153,162]. Although the exact mechanism of vertical transmission is unknown, intrapartum transmission probably results from infant mucosal exposure to maternal blood or cervicovaginal tract secretions during delivery [58]. Dendritic cells or macrophages are initially targeted by HIV, which transmit the virus to $CD4^+$ T cells [162]. The activation and direct infection of $CD4^+$ T cells result in high rates of viral production and dissemination throughout the body [163,164]. In individuals receiving suppressive antiretroviral therapy, HIV can establish a state of latent infection in resting memory $CD4^+$ T cells [165]. Viruses isolated in early vertical infection predominantly use the CCR5 coreceptor, although use of other receptors has been reported [166]. Regardless of the route of infection, the gastrointestinal lymphoid tissues are a major site of viral replication and persistence and loss of $CD4^+$ T lymphocytes throughout infection [167,168].

Perinatal HIV infection is characterized by plasma RNA levels that rapidly reach very high levels often exceeding $10^5$ to $10^7$ copies/mL [42,169–171]. In a study of 106 HIV-infected infants, the median plasma HIV RNA value at 1 month old was 318,000 copies/mL, and it was common to see viral levels that exceeded $10^6$ copies/mL. In the absence of antiretroviral therapy, the levels decrease only gradually over the first 24 to 36 months of life [172]. A continued decrease in plasma HIV-1 RNA levels (mean −0.2 to −0.3 log decline/yr) has been noted in vertically infected children through 5 to 6 years of age [171,172]. As in adults, higher viral loads correlate with a more rapid disease progression [169,173–176] whereas lower levels of plasma HIV RNA with HAART are associated with clinical benefit [177,178]. These data indicate that high viral load is a critical determinant of pediatric disease progression and provides a strong argument for early and aggressive intervention with antiretroviral therapy. The persistently high levels of plasma HIV RNA observed in vertically infected infants may be related to many factors, including the kinetics of viral replication, a large and renewable $CD4^+$ cell pool size, presence of an active thymus, and delayed or ineffective HIV-specific immune responses [166].

### IMMUNE ABNORMALITIES IN HUMAN IMMUNODEFICIENCY VIRUS INFECTION

Infection with HIV results in profound deficiencies in cell-mediated and humoral immunity caused by quantitative and qualitative defects, leading to a progressive dysfunction of the immune system with depletion of $CD4^+$ T cells. Compared with adults, $CD4^+$ T–cell depletion may be less striking in children because of their relative lymphocytosis. Flow cytometric analysis of lymphocyte subpopulations in healthy children revealed age-related changes in many of the different subgroups [179–181]. Comparison of lymphocyte subsets in HIV-infected versus noninfected children younger than 2 years showed no difference for absolute $CD8^+$ counts, but clearly decreased levels of $CD4^+$ cells [182]. In the absence of early antiretroviral therapy, an abnormal $CD4^+$ count (<10th percentile for uninfected children) was found in 83% of the infected children, and an abnormally low absolute $CD4^+$ count was observed in 67%. As in adults, the relative risks of death or disease progression are inversely related to the $CD4^+$ cell count, which is closely related to the viral load [171,176,183]. A rapid increase in HIV RNA levels correlates with early disease progression and loss of $CD4^+$ cells in vertically infected infants [183], suggesting that antiretroviral therapy should be started in early infection to preserve immune function.

Other immune abnormalities include decreased lymphocyte proliferation in response to an antigen, polyclonal B-cell activation resulting in hypergammaglobulinemia, and altered function of monocytes and neutrophils [184–187]. In the European Collaborative Study, hypergammaglobulinemia (IgG, IgM, and IgA) identified 77% of infected infants at age 6 months with 97% specificity [188]. In a group of 47 HIV-infected children (17 asymptomatic and 30 symptomatic), Roilides and coworkers [184] found an abnormality of at least one IgG subclass in 83%, including some patients who had IgG2, IgG4, or combined IgG2-IgG4 deficiencies. There was no clear correlation of the incidence of bacterial infections with specific subclass deficiencies.

### HUMAN IMMUNODEFICIENCY VIRUS–SPECIFIC IMMUNE CONTROL

Vertically infected infants face many challenges in mounting a specific immune response to HIV [5]. First, HIV transmission occurs before the immune system is fully developed in an infant allowing for more efficient viral replication and less efficient immunologic containment of the virus [5]. Second, infected infants carry a high frequency of

maternally inherited HLA class I alleles (e.g., HLA-B*1801 and HLA-B*5802) associated with poor control of HIV [189]. Third, transmitted maternal escape mutants are adapted to maternal HLA alleles and preadapted to the infant's HLA [190,191]. Finally, passive transfer of maternal, non-neutralizing antibodies could inhibit development of HIV-specific immune responses [192].

It is well established that the CD8$^+$ cytotoxic T lymphocytes (CTL) play a crucial role in generation of HIV-specific immune response in acute adult infection [192–195]. Although, HIV-1–specific CTL activity can be shown at a very early age, even in the fetus, the response is weak and less broad compared with adults with primary infection [196–200]. Because infants share at least three HLA class I alleles with their mothers, vertical transmission of maternal CTL escape mutants could affect the infant's ability to mount an early CTL response restricted by shared HLA alleles [191,201,202]. HIV-specific CTL responses become more frequent and broad in infected infants after 6 months of life [198,203]. More recent reports indicate that some CTL responses in infants can select for viral escape variants very early in life [204–206]. In addition, disease progression is slower in children who express HLA-B*27 or HLA-B*57 [206,207], indicating that CTL responses can have an important role in suppression of HIV in pediatric infection [5].

In neonates, defective, antibody-dependent, cell-mediated cytotoxicity of HIV-infected cells by natural killer cells has been reported [208]. After the decline of passively transferred maternal antibody-dependent, cell-mediated cytotoxicity antibodies, the production of HIV-envelope cytotoxic antibodies is delayed in vertically infected infants [209]. Although neutralizing antibodies can be generated during early infection [210–212] the precise role of neutralizing antibodies in limiting mother-to-child transmission of HIV is unclear [5].

Several studies indicate that HIV-infected children have reduced antibody responses to certain childhood vaccines (e.g., diphtheria, acellular pertussis vaccine) [209,213–215]. Reduced antibody responses after immunization and vaccine failures in HIV-infected infants may result from a poor primary immune response, failure to generate memory responses, or loss of memory cells [209]. Most vertically infected infants who receive HAART before 3 months of age develop antibody and lymphoproliferative responses to routine infant vaccines, although persistent HIV-specific immune responses are not detected [192,196,199,209]. More recent studies have reported a sustained increase in peripheral blood CD5 cell counts and robust immune reconstitution among HIV-infected children after prolonged HAART [216,217], permitting discontinuation of prophylactic therapy for opportunistic infections [218].

# DIAGNOSIS

## HUMAN IMMUNODEFICIENCY VIRUS TESTING OF PREGNANT WOMEN

Diagnosis of HIV infection as part of routine prenatal care of pregnant women is very important because preventive therapies are now widely available, even in developing countries [26]. The U.S. Centers of Disease Control and Prevention (CDC), the AAP, and the American College of Obstetricians and Gynecologists recommend documented, routine antenatal HIV testing for all women in the United States after notifying the patient that testing will be done unless the patient refuses HIV testing ("opt-out" approach with right of refusal) [219–221]. Repeat HIV testing is recommended in the third trimester for women at high risk of acquiring HIV infection [219–221]. Physicians should be aware of state and local laws, regulations, and policies related to rapid HIV testing of pregnant women and newborns.

Most commercially available enzyme immunoassays measure IgG antibodies to HIV. A positive enzyme immunoassay must be confirmed by a secondary test, typically a Western blot. Several rapid tests detect HIV antibodies, and most are highly sensitive and specific (99% to 100%). Rapid HIV testing is recommended for women presenting in labor with unknown HIV status so that intrapartum antiretroviral prophylaxis can be administered to the mother in a timely fashion [219–221]. All positive rapid tests must be confirmed by another test. Early identification of HIV infection in pregnant women is crucial to prevent perinatal HIV transmission and provides an opportunity to evaluate the infected woman's health and begin HAART if indicated [222,223]. Rapid HIV antibody testing should be performed on the infant if the mother's HIV status is unknown. If the infant's rapid HIV antibody test result is positive, antiretroviral prophylaxis should be administered to the infant as soon as possible after birth but certainly within 12 hours of life [220,224]. Rapid HIV antibody testing should be available at all health care facilities with maternity and neonatal units.

## EARLY INFANT DIAGNOSIS

Prenatal diagnosis in the fetus is difficult because of the risk for bleeding and contamination of the sample with maternal blood or the possibility for accidental iatrogenic infection of the fetus. Amniotic fluid has been found to be positive for p24 antigen and HIV reverse transcriptase [50,51]. Chorionic villus sampling and percutaneous umbilical blood sampling are associated with a higher risk for the fetus. Noninvasive techniques such as fetal ultrasonography or the clinical assessment of the mother give unspecific and not very predictive information.

Many advances have been made in the area of laboratory diagnosis of HIV infection [220,224–226]. Routine HIV antibody testing cannot be used in infants for the diagnosis of HIV infection because of transplacental passage of maternal IgG antibodies to the virus that are present in infants up to 18 months of age. The diagnosis of HIV infection has advanced from antibody and antigen detection to PCR-based DNA or RNA assays (referred to as HIV nucleic acid amplification tests) that are highly sensitive and specific [227,228] and now widely available in industrialized countries [220].

HIV-1 DNA PCR assay detects viral DNA in peripheral blood mononuclear cells and is frequently used in the United States for diagnosis of HIV in infants and children younger than 18 months; the sensitivity and

specificity of HIV-1 DNA PCR assays are 96% and 99% by 1 month of age for detection of HIV-1 subtype B [227,228]. HIV-1 DNA PCR assays are less sensitive for identifying non–B subtype virus, however, and have been associated with false-negative tests in patients with non–B subtype HIV-1 infection [229,230].

Plasma HIV-1 RNA PCR assay can also be used for early diagnosis of HIV-1 infection in infancy [220]. The HIV-1 RNA assay is as sensitive or more sensitive and as specific for detection of HIV-1 subtype B compared with HIV-1 DNA PCR [228,231–234]. False-positive results can occur, however [232,234,235]. Any positive test should be repeated for confirmation [236]. HIV-1 RNA PCR may be more sensitive than HIV-1 DNA PCR for detection of non–B subtype virus [234]. It is prudent to use HIV RNA PCR for diagnosis of infants born to women known or suspected to have non–B subtype HIV infection [220]. The sensitivity of HIV-1 RNA PCR is not affected by the presence of maternal or infant zidovudine prophylaxis [236].

HIV-1 DNA or RNA PCR testing is recommended at birth and 14 to 21 days of age, and if test results are negative, repeat testing is recommended at 1 to 2 months and at 4 to 6 months [220]. A cord blood specimen should not be used because of possible contamination with maternal blood. It is assumed that infants who have a positive HIV PCR result within the first 48 hours after birth were infected in utero, whereas infants who are infected during the intrapartum period might become positive 2 to 6 weeks after birth [59,237]. Testing HIV-exposed infants at birth with HIV DNA or RNA PCR may be considered if mothers did not receive antiretroviral drugs during pregnancy or in other high-risk scenarios [224]. Two separate positive HIV-1 DNA or RNA PCR tests are needed for diagnosis of HIV-1 infection in infants [220].

If infection is confirmed, the infant should be promptly referred to a pediatric HIV specialist for consideration of HAART and care [220] to prevent rapid disease progression noted in some vertically infected infants [238]. HIV-1 infection can be *presumptively excluded* in non–breast-feeding, HIV-exposed infants and children younger than 18 months with (1) two negative HIV-1 DNA or RNA PCR test results from separate specimens, both of which were obtained at 2 weeks or more of age and one of which was obtained at 4 weeks or more of age; or (2) one negative HIV-1 RNA or DNA PCR test result from a specimen obtained at 8 weeks or more of age; or (3) one negative HIV-1 antibody test obtained at 6 months or more of age [224]. HIV-1 infection can be *definitively excluded* in non–breast-feeding, HIV-exposed infants and children younger than 18 months with (1) two negative HIV-1 DNA or RNA PCR test results from separate specimens, both of which were obtained at 1 month or more of age and one of which was obtained at 4 months or more of age, or (2) two negative HIV-1 antibody tests from separate specimens, both of which were obtained at 6 months or more of age [220].

Many physicians confirm the absence of HIV infection by documenting a negative HIV-1 antibody test result at 12 to 18 months of age [220]. These laboratory tests can be used to exclude HIV-1 infection only if there is no other laboratory (e.g., no subsequent positive PCR test results if performed) or clinical (e.g., no AIDS-defining illness) evidence of HIV-1 infection.

Virtually all infants born to seropositive mothers are positive for HIV antibodies at birth, even though only a few are infected. Of uninfected infants, 75% lose these passively transferred antibodies between 6 and 12 months of age, but persistence of maternal antibodies has been documented in 2% up to 18 months of age [239]. Many physicians confirm the absence of HIV infection by documenting a negative HIV-1 antibody test result at 12 to 18 months of age [220]. If HIV-1 antibody testing is performed at 12 months of age in an infant exposed to HIV but not known to be infected, and if still antibody positive, repeat testing at 18 months of age is recommended [220]. Detection of HIV-1 antibody in a child 18 months of age or older is diagnostic of HIV-1 infection. Documentation of seroreversion may be more important when non–subtype B HIV-1 is possible or present.

HIV-1 culture is as sensitive as HIV-1 DNA PCR assay, but it is more expensive and needs a specialized laboratory, and results are unavailable for 2 to 3 weeks [240]. Use of HIV-1 p24 antigen detection is not recommended for diagnosis of infant HIV-1 because of its poor sensitivity [241].

Clinical and nonspecific laboratory parameters may also suggest HIV infection. Hypergammaglobulinemia is a nonspecific but early finding of HIV infection, and $CD4^{+}$ counts must be interpreted within the bounds of the age-dependent normal range [179–181,242] In 1994, the CDC published revised guidelines for the diagnosis of HIV infection in infants and children younger than 13 years (Table 21–1) [243]. No changes have been made to the AIDS surveillance case definition for children younger than 18 months [244]. Table 21–2 provides a diagram outlining the initial evaluation and the necessary follow-up tests for an asymptomatic infant born to an HIV-positive mother, as recommended by the AAP [220].

## CLASSIFICATION OF HUMAN IMMUNODEFICIENCY VIRUS INFECTION IN CHILDREN

In 1994, the CDC published a revised pediatric classification system for HIV infection in children younger than 13 years based on clinical disease and immunologic status (Table 21–3) [243]. Clinical categories range from *N*, indicating no signs or symptoms, through *A*, *B*, and *C*, for mild, moderate, and severe (AIDS-defining) symptoms and signs. Diagnosis is established if an AIDS-defining disease occurs (Table 21–4) [246]. In the pre-HAART era, *Pneumocystis jiroveci* (formerly *carinii*) pneumonia (PCP) pneumonia was the leading AIDS-defining illness diagnosed during the first year of life and associated with a high mortality rate [245]. Other common AIDS-defining conditions in U.S. children with vertically acquired infection include lymphoid interstitial pneumonitis, multiple or recurrent serious bacterial infections, HIV encephalopathy, wasting syndrome, *Candida* esophagitis, cytomegalovirus disease, and *Mycobacterium avium-intracellulare* complex infection (see Table 21–4) [246].

The immunologic categories place an emphasis on the $CD4^{+}$ T-lymphocyte count and percentages for age and

**TABLE 21–1** Centers for Disease Control and Prevention Definition of Human Immunodeficiency Virus Infection in Children Younger than 13 Years of Age

| ***HIV Infected*** |
|---|
| A. Child <18 mo old who is known to be HIV-seropositive or born to HIV-infected mother |
| *and* |
| Has positive results on two separate determinations (excluding cord blood) from one or more of the following HIV detection tests: |
| HIV polymerase chain reaction |
| HIV culture |
| HIV antigen (p24) |
| *or* |
| Meets criteria for AIDS diagnosis based on 1987 AIDS surveillance case definition |
| B. Child >18 mo old born to HIV-infected mother or any child infected by blood, blood products, or other known modes of infection who |
| Is HIV antibody–positive by repeatedly reactive EIA and confirmatory test (e.g., Western blot or immunofluorescence assay) |
| *or* |
| Meets any of the criteria in A |
| ***Perinatally Exposed (Prefix E)*** |
| A child who does not meet the above-listed criteria and who |
| Is HIV-seropositive by EIA and confirmatory test and is <18 mo old |
| *or* |
| Has unknown antibody status, but was born to a mother known to be HIV infected |
| ***Seroreverter (SR)*** |
| Child who is born to HIV-infected mother and who |
| Has been documented as HIV antibody–negative (i.e., two or more negative EIA tests performed at age 6-18 mo or one negative EIA test performed after age 18 mo) |
| *or* |
| Has had no laboratory evidence of infection |
| *and* |
| Has not had an AIDS-defining condition |

*EIA, enzyme immunoassay.*

| | **Infant Age** | | | | | | |
|---|---|---|---|---|---|---|---|
| **Test** | **Birth** | **2 wk** | **4 wk** | **6 wk** | **2 mo** | **4 mo** | **12-18 mo** |
| History and physical examination (including weight, height, head circumference)[*] | + | + | + | | | | |
| Assess risk of other infections | + | | | | | | |
| Antiretroviral prophylaxis | + | | | +[†] | | | |
| Formula feeding | + | + | + | + | + | + | + |
| Complete blood cell count | + | | + | | +[‡] | | |
| HIV-1 DNA or RNA PCR[§] | +[¶] | + | | + | | + | |
| PCP prophylaxis | | | | +[#] | | | |
| HIV-1 antibody testing | | | | | | | +[**] |

[*] *Review maternal history for possible exposure to coinfections (e.g., tuberculosis, syphilis, herpes simplex virus, cytomegalovirus, or hepatitis B virus).*
[†] *Zidovudine to prevent perinatal transmission should be started soon after birth but certainly within 12 hr. Zidovudine is discontinued at 6 wk of age; however, other antiretroviral therapy should be started in a child who is proved to be infected according to pediatric treatment guidelines with close laboratory monitoring.*
[‡] *Complete blood cell count is measured at 4 wk and rechecked at 8 wk if severe anemia was noted at the 4-wk visit.*
[§] *Repeat polymerase chain reaction (PCR) immediately if positive to confirm infection. If the initial test is negative, repeat test at 4 wk to 2 mo and 4-6 mo of age to identify or exclude HIV-1 infection as early as possible.*
[¶] *Consider obtaining birth HIV DNA or RNA PCR test to exclude intrauterine HIV infection if the mother did not receive highly active antiretroviral therapy during pregnancy or in other high-risk situations.*
[#] Pneumocystis jiroveci (*formerly* carinii) *pneumonia (PCP) prophylaxis should be continued for 1 year if infant is diagnosed with HIV.*
[**] *HIV-1 antibody testing is performed to confirm the absence of HIV infection.*

**TABLE 21–3** 1994 Centers for Disease Control and Prevention Revised Classification System for Human Immunodeficiency Virus Infection in Children Younger than 13 Years of Age

Using this system, children are classified according to three parameters: infection status, clinical status, and immunologic status. The categories are mutually exclusive. When classified in a more severe category, a child is not reclassified in a less severe category even if the clinical or immunologic status improves.*

***Pediatric HIV Classification***

| | Clinical Categories | | | |
|---|---|---|---|---|
| **Immune Categories** | **No Symptoms (N)** | **Mild Symptoms (A)** | **Moderate Symptoms (B)†** | **Severe Symptoms (C)†** |
| No suppression (1) | N1 | A1 | B1 | C1 |
| Moderate suppression (2) | N2 | A2 | B2 | C2 |
| Severe suppression (3) | N3 | A3 | B3 | C3 |

***Immunologic Categories Based on Age-Specific $CD4^+$ T Lymphocyte Counts and Percent of Total Lymphocytes***

The immunologic category classification is based on age-specific $CD4^+$ T lymphocyte count or percent of total lymphocytes and is designed to determine severity of immunosuppression attributable to HIV for age. If either $CD4^+$ count or percent results in classification into a different category, the child should be classified into the more severe category. A value should be confirmed before the child is reclassified into a less severe category.

| | Age Groups | | |
|---|---|---|---|
| **Immunologic Category** | **0-11 mo** | **1-5 yr** | **>6 yr** |
| No suppression (1) | >1500 cells/μL (>25%) | >1000 cells/μL (>25%) | >500 cells/μL (>25%) |
| Moderate suppression (2) | 750-1499 cells/μL (15%-24%) | 500-999 cells/μL (15%-24%) | 200-499 cells/μL (15%-24%) |
| Severe suppression (3) | <750 cells/μL (<15%) | <500 cells/μL (<15%) | <200 cells/μL (<15%) |

***Clinical Categories for Children with HIV Infection***

**Category N: Not Symptomatic**

Children who have no signs or symptoms considered to be the result of HIV infection or who have only one of the conditions listed in category A

**Category A: Mildly Symptomatic**

Children with two or more of the following conditions, but none of the conditions listed in categories B and C:

- Lymphadenopathy (>0.5 cm at more than two sites; bilateral = one site)
- Hepatomegaly
- Splenomegaly
- Dermatitis
- Parotitis
- Recurrent or persistent respiratory infection, sinusitis, or otitis media

**Category B: Moderately Symptomatic**

Children who have symptomatic conditions other than those listed for category A or C that are attributed to HIV infection

Examples of conditions in clinical category B include but are not limited to:

- Anemia (<8 g/dL), neutropenia (<1000/$mm^3$), or thrombocytopenia (<100,000/$mm^3$) persisting >30 days
- Bacterial meningitis, pneumonia, or sepsis (single episode)
- Candidiasis, oropharyngeal thrush, persisting for >2 mo in children >6 mo old
- Cardiomyopathy
- Cytomegalovirus infection, with onset before 1 mo of age
- Diarrhea, recurrent or chronic
- Hepatitis
- Herpes simplex virus stomatitis, recurrent (more than two episodes within 1 yr)
- Herpes simplex virus bronchitis, pneumonitis, or esophagitis with onset before 1 mo of age
- Herpes zoster (shingles) involving at least two distinct episodes or more than one dermatome
- Leiomyosarcoma
- Lymphoid interstitial pneumonia or pulmonary lymphoid hyperplasia complex
- Nephropathy
- Nocardiosis
- Persistent fever (lasting >1 mo)
- Toxoplasmosis, onset before 1 mo of age
- Varicella, disseminated (complicated chickenpox)

*Continued*

**TABLE 21–3** 1994 Centers for Disease Control and Prevention Revised Classification System for Human Immunodeficiency Virus Infection in Children Younger than 13 Years of Age—cont'd

| | Age Groups | | |
|---|---|---|---|
| **Immunologic Category** | **0-11 mo** | **1-5 yr** | **>6 yr** |
| **Category C: Severely Symptomatic**[†] | | | |
| Children who have any condition listed in the 1987 surveillance case definition for AIDS, with the exception of lymphoid interstitial pneumonia | | | |
| Serious bacterial infections, multiple or recurrent (i.e., any combination of at least two culture-confirmed infections within a 2-yr period of the following types: septicemia, pneumonia, meningitis, bone or joint infection, or abscess of an internal body organ or body cavity, excluding otitis media, superficial skin or mucosal abscesses, and indwelling catheter-related infections) | | | |
| Candidiasis, esophageal or pulmonary (bronchi, trachea, lungs) | | | |
| Coccidioidomycosis, disseminated (at site other than or in addition to lungs or cervical or hilar nodes) | | | |
| Cryptosporidiosis or isosporidiosis with diarrhea persisting >1 mo | | | |
| Cytomegalovirus disease with onset of symptoms at age >1 mo (other than liver, spleen, or lymph nodes) | | | |
| Encephalopathy (at least one of the following progressive findings present for at least 2 mo in the absence of a concurrent illness other than HIV infection that could explain the findings): (1) failure to attain or loss of developmental milestones or loss of intellectual ability verified by standard developmental scale or neuropsychologic tests; (2) impaired brain growth or acquired microcephaly shown by head circumference measurements or brain atrophy shown by CT or MRI (serial imaging is required for children <2 yr old); (3) acquired symmetric motor deficit manifested by two or more of the following: paresis, pathologic reflexes, ataxia, or gait disturbance | | | |
| Herpes simplex virus infection causing a mucocutaneous ulcer that persists for >1 mo or bronchitis, pneumonitis, or esophagitis for any duration affecting a child >1 mo old | | | |
| Histoplasmosis, disseminated (other than or in addition to lungs or cervical lymph nodes) | | | |
| Kaposi sarcoma | | | |
| Lymphoma, primary, in brain | | | |
| Lymphoma, small, noncleaved cell (Burkitt), or immunoblastic or large cell lymphoma of B cell or unknown immunologic phenotype | | | |
| *Mycobacterium tuberculosis*, disseminated or extrapulmonary | | | |
| *Mycobacterium*, other species or unidentified species, disseminated (other than or in addition to lungs, skin, or cervical or hilar lymph nodes) | | | |
| *Mycobacterium avium-intracellulare* complex or *Mycobacterium kansasii*, disseminated (other than or in addition to lungs, skin, or cervical or hilar lymph nodes) | | | |
| *Pneumocystis jiroveci* (formerly *carinii*) pneumonia | | | |
| Progressive multifocal leukoencephalopathy | | | |
| *Salmonella* (nontyphoid) septicemia, recurrent | | | |
| Toxoplasmosis of the brain with onset >1 mo of age | | | |
| Wasting syndrome in the absence of a concurrent illness other than HIV infection that could explain the following findings: persistent weight loss >10% of baseline *or* downward crossing of at least two of the following percentiles on weight-for-height chart on two consecutive measurements >30 days apart *plus* chronic diarrhea (i.e., at least two loose stools per day for >30 days) *or* documented fever (for >30 days, intermittent or constant) | | | |

**Children whose HIV infection status is not confirmed are classified by using the grid with a letter* E *(for vertically exposed) placed before the appropriate classification code (e.g.,* EN2).
[†]*Category C and lymphoid interstitial pneumonitis in category B are reportable to state and local health departments as AIDS.*
*From Centers for Disease Control and Prevention. Recommendations of the U.S. Public Health Service Task Force on the use of zidovudine to reduce perinatal transmission of human immunodeficiency virus. MMWR Morb Mortal Wkly Rep 43:1-20, 1994.*

include stage 1, no evidence of immunosuppression; stage 2, moderate immunosuppression; and stage 3, severe immunosuppression [243]. After being classified, a child cannot be reclassified into a less severe category, even if the child's clinical status or immune function improves in response to antiretroviral treatment or resolution of clinical events. HIV-exposed infants whose HIV infection status is indeterminate (unconfirmed) are classified by placing a prefix *E* (for perinatally exposed) before the appropriate classification code (e.g., EN2) [243].

The current AIDS case definitions devised by the CDC for surveillance and reporting purposes are similar with some important exceptions [247]. Lymphoid interstitial pneumonitis and multiple or recurrent serious bacterial infections are AIDS-defining illnesses only for children. Also, certain herpesvirus infections (cytomegalovirus, herpes simplex virus) and toxoplasmosis of the central nervous system are AIDS-defining conditions only for adults and children older than 1 month. In 1994, the CDC published a revised pediatric classification system for HIV infection in children younger than 13 years according to the following parameters: (1) HIV infection status, (2) clinical disease, and (3) immunologic status [243].

HIV infection in infants and children has a different presentation from that in adults [5]. Children are more likely than adults to have serious bacterial infections, and lymphocytic interstitial pneumonitis is almost entirely restricted to the pediatric age group. Opportunistic infections such as PCP often manifest as primary diseases with a more aggressive course because of lack of prior immunity [245]. Toxoplasmosis; cryptococcal infection; and the occurrence of cancer, especially Kaposi sarcoma, are less common in HIV-infected children [5,246].

In developing countries with limited diagnostic resources, the diagnosis often has to be based on clinical symptoms, and a modified provisional definition for pediatric cases of AIDS has been issued by the WHO [248]. Evaluations of clinical staging systems for the diagnosis

**TABLE 21–4** AIDS Indicator Diseases Diagnosed in 8086 Children Younger than Age 13 Years Reported to the Centers for Disease Control and Prevention through 1997

| Disease | No. Children Diagnosed | Percent of Total* |
|---|---|---|
| *Pneumocystis jiroveci* (formerly *carinii*) pneumonia | 2700 | 33 |
| Lymphocytic interstitial pneumonitis | 1942 | 24 |
| Recurrent bacterial infections | 1619 | 20 |

| Encephalopathy | 1322 | 16 |
| *Candida* esophagitis | 1266 | 16 |
| Cytomegalovirus disease | 658 | 8 |
| *Mycobacterium avium* infection | 639 | 8 |
| Severe herpes simplex infection | 370 | 5 |
| Pulmonary candidiasis | 307 | 4 |
| Cryptosporidiosis | 291 | 4 |
| Cancer | 162 | 2 |

**The sum of percentages is greater than 100 because some patients have more than one disease. From Centers for Disease Control and Prevention (CDC). U.S. HIV and AIDS cases reported through December 1997. HIV/AIDS Surveillance report: year-end edition. MMWR Morb Mortal Wkly Rep 9:1-44, 1997.*

of HIV in early infancy have reported limited sensitivity in sub-Saharan Africa, however [249–251]. The WHO has published revised case definitions of HIV infection for surveillance and a revised clinical staging and immunologic classification of HIV disease in adults and children [252].

## CLINICAL MANIFESTATIONS AND PATHOLOGY

The clinical manifestations of HIV infection in infants are highly variable and often nonspecific [253]. Infants with perinatally acquired HIV infection are often asymptomatic, and physical examination is usually normal in the neonatal period. Although a distinctive craniofacial dysmorphism characterized by a prominent boxlike forehead, hypertelorism, flattened nasal bridge, triangular philtrum, and patulous lips was suggested as a possible congenital HIV syndrome [254], these findings have not been confirmed in subsequent reports [255]. In a prospective cohort study of 200 perinatally acquired HIV-1 infections, the median age of onset of any HIV-related symptom or sign was 5.2 months; the probability of remaining asymptomatic was 19% at 1 year and 6.1% at 5 years [256]. In another large prospective cohort study, AIDS-defining conditions developed in approximately 23% and 40% of perinatally infected infants by 1 and 4 years [246,257].

The initial symptoms of HIV infection in infants may be subtle and sometimes difficult to distinguish from manifestations caused by drug use during pregnancy, from problems associated with prematurity, or from congenital infections other than HIV. Premature birth has been reported in 19%, with no difference between children born to drug-using mothers and children of mothers who were infected through other routes [188,258]. Children of drug-addicted mothers had significantly lower birth weights and smaller head circumferences, however.

Growth delay is an early and frequent finding of untreated perinatal HIV infection, and linear growth is most severely affected in children with high viral loads [259]. Common clinical features seen during the first year of life include lymphadenopathy and hepatosplenomegaly. Other manifestations noted during the course of HIV infection in children are failure to thrive, unexplained persistent fevers, developmental delay, encephalopathy, recurrent and chronic otitis media and sinusitis, recurrent invasive bacterial infections, opportunistic infections, chronic diarrhea, presence and persistence of oral candidiasis, parotitis, cardiomyopathy, nephropathy, and many nonspecific cutaneous manifestations [260].

## INFECTIOUS COMPLICATIONS

Infections in HIV-infected infants not receiving antiretroviral therapy can be serious or life-threatening. The difficulty in treating these infectious episodes, their chronicity, and their tendency to recur distinguish them from the normal infections of early infancy. It is helpful to document each episode and to evaluate the course and frequency of their recurrences. With early diagnosis and access to antiretroviral treatment, opportunistic infections rarely develop in HIV-infected children living in the United States.

### Bacterial Infections

Recurrent serious bacterial infections, such as meningitis, sepsis, and pneumonia, are so typical of HIV infection in children that they were included in the revised CDC definition of 1987 [247,261]. Recurrent bacterial infections accounted for 18% of all pediatric AIDS-defining conditions reported to the CDC in 1997. *Streptococcus pneumoniae* is the most frequent cause of serious bacterial infection in children infected with HIV. In a study of 42 vertically infected children, a mean of 1.8 febrile visits per child-year of observation was reported [262]. Eleven of the 27 positive blood cultures grew *S. pneumoniae*, and 16 grew organisms that were considered central venous line–related (coagulase-negative staphylococci, gram-negative enterics, *Staphylococcus aureus*, *Pseudomonas aeruginosa*, and *Candida* species). This increased incidence of pneumococcal infections has been confirmed by other studies [263,264].

Infections in HIV-infected newborns have the same pattern as seen commonly in the neonatal period. A syndrome of very-late-onset group B streptococcal disease (at 3½ to 5 months of age) has been described in HIV-infected children [265]. Other rare infections, such as congenital syphilis or neonatal gonococcal disease, may become more frequent in the future as the incidence increases among pregnant women [266–269]. Congenital syphilis may be missed if serologic tests are not performed on the mother and child at the time of delivery and repeated later if indicated.

Mycobacterial infections have assumed an increasingly important role in the pathology of HIV-infected infants and children. Although the number of HIV-infected children with *Mycobacterium tuberculosis* infection is still small, organisms resistant to multiple antituberculosis drugs cultured from adults and children pose a threat not only

to other immunocompromised patients, but also to health care providers [270–273]. An important issue for the neonatologist is whether the mother is infected with M. tuberculosis and may transmit the disease to her child. The diagnosis of *M. tuberculosis* infection is complicated in HIV-infected patients because of the frequent anergy leading to a negative Mantoux test result even in the presence of infection. To diagnose anergy, a control (e.g., for mumps, *Candida*, or tetanus) should always be placed simultaneously with the Mantoux test [274]. Treatment of *M. tuberculosis* infection in children is complicated by the lack of pediatric formulations, but usually includes isoniazid, rifampin, and, during the first 2 months, pyrazinamide [275].

Infection with *M. avium-intracellulare* complex occurs in almost 20% of HIV-infected children with advanced disease and manifests as nonspecific symptoms such as night sweats, weight loss, and low-grade fevers [276,277]. Treatment usually consists of three or more drugs (e.g., clarithromycin, ethambutol, rifampin or amikacin or both, ciprofloxacin, clofazimine), but commonly provides only temporary symptomatic relief and not eradication of the infection. Prophylaxis with clarithromycin or azithromycin should be initiated in infants younger than 1 year with a $CD4^+$ count less than 750 cells/mm$^3$, in children 1 to 2 years old with a $CD4^+$ count less than 500 cells/mm$^3$, and in children 2 to 6 years old with a $CD4^+$ count less than 75 cells/mm$^3$. In children older than 6 years, the adult threshold of 50 cells/mm$^3$ can be used [278].

## Viral Infections

Viral infections are important causes for morbidity and mortality in HIV-infected children. Primary varicella can be unusually severe and can recur as zoster, often manifesting with very few, atypical lesions. The virus may become resistant to standard treatment with acyclovir [279–281]. Cytomegalovirus infection can result in esophagitis, hepatitis, enterocolitis, or retinitis [282–285]. Cytomegalovirus can become resistant to treatment with ganciclovir, necessitating the use of foscarnet or combination regimens [286,287].

Other commonly encountered viruses in HIV-infected infants and children are hepatitis A, B, and C, often associated with a more fulminant or chronic aggressive course than in non–HIV-infected patients [288–290]. Hepatitis C infection has been shown to be more common in children born to HIV-infected mothers in some studies [290], but others have found no association between maternal HIV status and perinatal hepatitis C transmission [291,292].

Infection with the measles virus is associated with a high mortality in HIV-infected children and often manifests without the typical rash and can result in fatal giant cell pneumonia [293–296]. Infection with respiratory syncytial virus or adenovirus, alone or in combination, can also result in rapid and sometimes fatal respiratory compromise and in chronic or persistent viral shedding or infection [297–299].

The occurrence of a polyclonal lymphoproliferative syndrome is often associated with evidence of primary or reactivated Epstein-Barr virus infection. These patients develop impressive lymphadenopathy and sometimes have concurrent lymphocytic interstitial pneumonitis or parotitis [300]. The distinction between a self-limited, benign hyperproliferation and the development of a monoclonal lymphoid malignancy is crucial for determining treatment and prognosis.

## Fungal and Protozoal Infections

Oral candidiasis is common even in healthy, non–HIV-infected newborns and infants. Infection beyond infancy, involvement of pharynx and esophagus, and persistence despite treatment with antifungal agents are more typical for immunocompromised children. Disseminated candidiasis is uncommon, however, in the absence of predisposing factors, such as central venous catheters or total parenteral nutrition [301].

Although infection with *Cryptococcus neoformans* is common in adults with HIV infection, it is less common in children [302,303]. Colonization with *Aspergillus* species and invasive disease has been described in adult patients with HIV infection, and we have observed at least one infant with perinatally acquired HIV infection and associated myelodysplastic syndrome who developed fatal pulmonary aspergillosis [304–306]. The incidence of other fungal infections varies with the prevalence of the organism in the specific geographic area. Disseminated histoplasmosis as the AIDS-defining illness has been described in a few infants [307–309].

Early in the HIV epidemic, PCP was the AIDS indicator disease in almost 40% of the pediatric cases reported to the CDC [245]. This situation has changed dramatically, however, since the introduction of guidelines for PCP prophylaxis in HIV-exposed infants and HIV-infected children, and PCP accounted for only 25% of the AIDS cases in 1997 [310,311]. The peak incidence of PCP in infancy occurs during the first 3 to 6 months of life, often as the first symptom of HIV infection. Presumably, PCP represents primary infection in these infants. At least one case of maternal-to-fetal transmission of PCP has also been documented [312].

Most children with PCP present with an acute illness, with hypoxemia, and without a typical radiographic picture [313,314]. The diagnosis is usually made by obtaining an induced sputum (which can be done by experienced therapists even in very young children) or by performing a bronchoalveolar lavage, and an open lung biopsy is only rarely necessary [315,316]. Treatment options are high-dose intravenous trimethoprim-sulfamethoxazole (TMP-SMX) and pentamidine as first-line drugs [317]. Early adjunctive treatment with corticosteroids has been beneficial in adults and children with moderate to severe PCP and is commonly recommended for patients with an initial arterial oxygen pressure of less than 70 mm Hg or an arterial-alveolar gradient of more than 35 mm Hg [318–321].

PCP has been associated with a mortality of 39% to 65% in infants despite improved diagnosis and treatment [322,323]. In 1991, the CDC issued guidelines for PCP prophylaxis in children, taking into account the age-dependent levels of normal $CD4^+$ cell numbers [324]. These recommendations were applicable, however, only if a child was known to be HIV infected. A survey

published in 1995 revealed basically no change between 1988 and 1992 in the incidence of PCP among infants born to HIV-infected mothers [325]. Two thirds of these infants had never received PCP prophylaxis, and 59% were recognized as having been exposed to HIV infection within 30 days or less of PCP diagnosis. Among the infants known to be HIV infected who had a $CD4^+$ count performed within 1 month of PCP diagnosis, 18% had a $CD4^+$ count greater than 1500 cells/mm$^3$, the recommended threshold for initiation of PCP prophylaxis [325]. At the same time, it was shown that primary prophylaxis during the first year of life was highly effective in the prevention of PCP [326]. These pivotal studies led to revised guidelines in 1995 [310]. The major new recommendation was that all infants born to HIV-infected women should be started on PCP prophylaxis at 4 to 6 weeks of age, regardless of their $CD4^+$ counts (Table 21–5) [218].

The recommended prophylactic regimen is TMP-SMX with 150 mg/m$^2$/day of TMP and 750 mg/m$^2$/day of SMX given orally in divided doses twice each day during 3 consecutive days per week. The alternative regimen is TMP-SMX given once daily for 3 days per week or twice daily 7 days per week [220]. If TMP-SMX is not tolerated, alternative regimens are dapsone taken orally (2 mg/kg once daily or 4 mg/kg once weekly) or intravenous pentamidine (4 mg/kg every 2 to 4 weeks) or atovaquone (30 mg/kg once daily for infants 1 to 3 months of age and 45 mg/kg once daily for infants 4 to 24 months) [220]. Breakthrough infections can occur with every regimen, however, and seem to be most frequent with intravenous pentamidine and least common with TMP-SMX [327,328].

Encephalitis caused by *Toxoplasma gondii* is common in adults with HIV infection, but only rarely seen in children [218]. Several case reports of *T. gondii* encephalitis in infants between 5 weeks and 18 months old have been published, however. Some of these infants probably acquired *Toxoplasma* infection in utero [329,330]. Toxoplasmosis is an important differential diagnosis in a patient with an intracerebral mass.

Protozoal infections of the gastrointestinal tract often represent difficult diagnostic and therapeutic problems and can be associated with an intractable diarrhea. Infection with *Cryptosporidium* has a prevalence of 3% to 3.6% among children with diarrhea [331]. HIV-infected children are at risk for prolonged diarrheal disease with often severe wasting.

## ENCEPHALOPATHY

Encephalopathy, often with early onset, was a frequent and typical manifestation of HIV infection in children before the introduction of antiretroviral therapy. Symptoms of encephalopathy in the newborn or young infant initially include delayed head control or delayed acquisition of a social smile and variable degrees of truncal hypotonia [332–334]. Subsequently, impairment of cognitive, behavioral, and motor functions becomes apparent. Typical findings include a loss of or failure to attain normal developmental milestones; weakness; intellectual deficits; or neurologic symptoms such as ataxia and pyramidal tract signs, including spasticity or rigidity [335]. Seizures are rare, but have been described, and cerebrovascular disease resulting in strokes or the formation of giant aneurysms at the base of the brain has been reported [336,337].

The course can be static, wherein the child attains milestones, albeit at a slower rate than normal for age, or the development can reach a plateau and then the child ceases to acquire new milestones. The most severe form is manifested by a subacute-progressive course in which the

**TABLE 21–5** Recommendations for *Pneumocystis jiroveci* (formerly *carinii*) Pneumonia (PCP) Prophylaxis and $CD4^+$ Monitoring in HIV-Exposed Infants and HIV-Infected Children

| Age/HIV Infection Status | PCP Prophylaxis | $CD4^+$ Monitoring |
|---|---|---|
| Birth to 4-6 wk, HIV exposed or infected | No prophylaxis (because PCP is rare and because of concerns regarding kernicterus with TMP-SMX) | 1 mo |
| 4-6 wk to 4 mo, HIV exposed or infected | Prophylaxis* | 3 mo |
| 4-12 mo | | |
| HIV infection presumptively excluded† | No prophylaxis | None |
| HIV infection indeterminate | Prophylaxis | 6, 9, 12 mo |
| HIV infected | Prophylaxis | 6, 9, 12 mo |
| 1-5 yr, HIV infected | Prophylaxis if<br>$CD4^+$ count is <500 cells/mm$^3$ *or*<br>$CD4^+$ percentage is <15% | Every 3-4 mo (more frequently if indicated) |
| >6 yr, HIV infected | Prophylaxis if<br>$CD4^+$ count <200 cells/mm$^3$ *or*<br>$CD4^+$ percentage is <15% | Every 3-4 yr |

**PCP prophylaxis is not needed if HIV RNA or DNA polymerase chain reaction (PCR) result is negative at 14 days and 4 wk of age. If no testing was performed before this, or only a single test was performed between 14 days and 6 weeks of age, PCP prophylaxis is started at this point until HIV infection is presumptively excluded.*

*†HIV-1 infection can be* presumptively excluded *in non–breast-feeding HIV-exposed infants and children <18 mo old if (1) two negative HIV-1 DNA or RNA PCR test results from separate specimens, both of which were obtained at ≥2 wk of age and one of which was obtained at ≥4 wk of age, or (2) one negative HIV-1 RNA or DNA PCR test result from a specimen obtained at ≥8 wk of age, or (3) one negative HIV-1 antibody test obtained ≥6 mo of age[224].*

*TMP-SMX, trimethoprim-sulfamethoxazole.*

child loses previously acquired capabilities [338,339]. Older children have impaired expressive language function, whereas receptive language seems to be slightly less affected [340,341]. Physical examination can reveal hypotonia or spasticity, and microencephaly may be present. Radiologic examination can suggest cerebral atrophy, calcifications in the basal ganglia and periventricular frontal white matter, and decreased attenuation in the white matter (Fig. 21–1) [342–346].

HIV-1 can be found in brain monocytes, macrophages, and microglia, and limited expression of the regulatory gene *nef*, but not of structural gene products, has been shown in astrocytes [347–350]. Analysis of cerebrospinal fluid revealed HIV RNA in 90% of samples, and more than 10,000 copies/mL were associated with severe neurodevelopmental delay [351,352]. It is likely that immune-mediated mechanisms or the secretion of toxic cytokines by infected cells contributes to the pathogenesis of central nervous system disease in AIDS patients [353]. The level of quinolinic acid, a neurotoxin that has been implicated in the development of HIV-related encephalopathy, is elevated in children with symptomatic central nervous system disease and decreased during treatment with zidovudine [354,355].

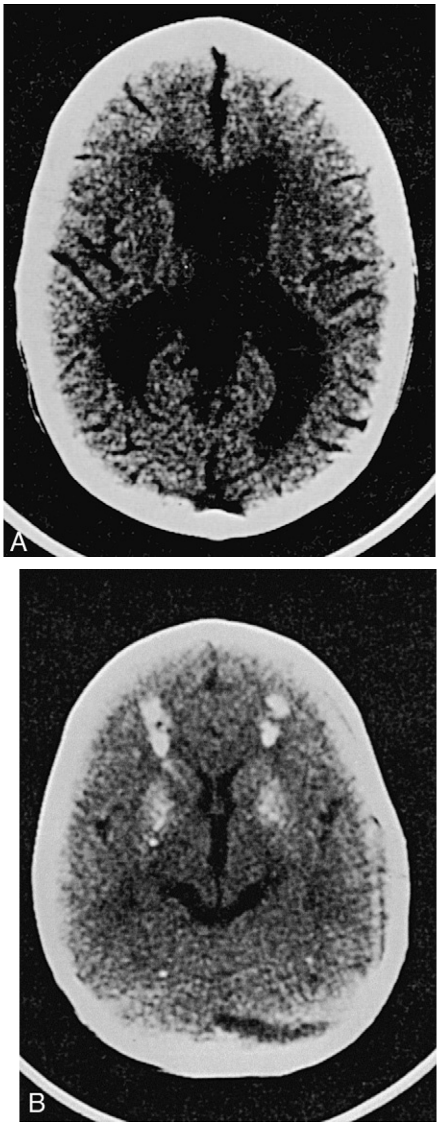

**FIGURE 21–1 CT scans of the brains of two infants with HIV-associated encephalopathy. A,** Cerebral atrophy with enlarged ventricles and widened sulci. **B,** Calcifications in basal ganglia and frontal white matter.

Postmortem examination shows variable degrees of white matter abnormalities, calcific deposits in the wall of blood vessels of the basal ganglia and the frontal white matter, and subacute encephalitis. At least one report described HIV-related meningoencephalitis in a newborn, supporting the assumption of an intrauterine infection [356]. Spinal cord disease, manifested by vacuolar myelopathy, has been described in children, but is less common than in adults [357].

Dramatic improvements in the degree of encephalopathy have been achieved by treating children with zidovudine, especially when given as a continuous intravenous infusion (see later) [358]. Therapy with corticosteroids has also been shown to be beneficial in some patients [359].

## OPHTHALMOLOGIC PATHOLOGY

Ophthalmologic complications associated with HIV infection can be particularly devastating. HIV-1 can infect the retina and manifest as cotton-wool spots on examination, but it rarely leads to impaired vision [360,361]. Several other pathogens, some of them acquired in utero, can affect the eye, however, and affect visual acuity. The incidence of blindness remains low in pediatric AIDS patients, but infections caused by herpesviruses and especially cytomegalovirus retinitis can be difficult to control and require intensive intravenous treatment [282,284,285]. A few children have been described with congenital toxoplasmosis and associated chorioretinitis, and an extrapulmonary manifestation of *P. jiroveci* infection is involvement of the retina [362–364]. Early recognition and aggressive intervention are crucial to prevent progression of visual impairment, and routine ophthalmologic examinations should be part of the care of all HIV-infected children.

## INTERSTITIAL LUNG DISEASE

Lymphocytic interstitial pneumonitis, or pulmonary lymphoid hyperplasia, is seen almost exclusively in the pediatric patient with HIV infection and is still included into the CDC definition of AIDS-defining diseases for children younger than 13 years (see Table 21–3). The incidence of lymphocytic interstitial pneumonitis is difficult to assess, but may affect 50% of HIV-infected children [365]. Clinically, there is a wide spectrum in the severity of this disease; a child may be asymptomatic with only radiologic changes, or he or she can become severely compromised with exercise intolerance or with oxygen dependency and the need for high-dose corticosteroid therapy. Children with lymphocytic interstitial pneumonitis are at higher risk to develop frequent bacterial and viral infections [366].

A diffuse, interstitial, often reticulonodular infiltrative process is typically observed on radiologic examination and is sometimes associated with hilar or mediastinal

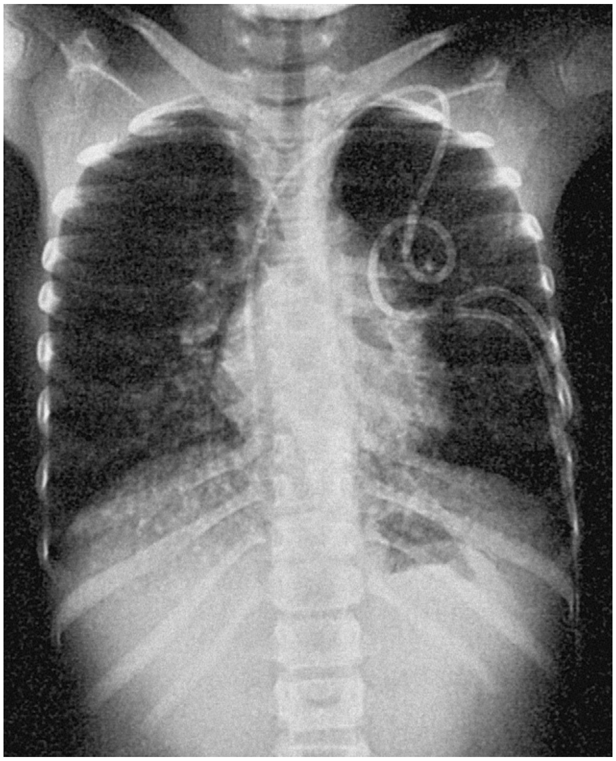

**FIGURE 21–2** Chest radiograph of an 8-year-old girl with severe lymphocytic interstitial pneumonitis who is oxygen and steroid dependent.

lymphadenopathy (Fig. 21–2) [365]. On biopsy, peribronchiolar lymphoid aggregates or a diffuse lymphoid infiltration of the alveolar septa and peribronchiolar areas is seen [300]. Treatment of lymphocytic interstitial pneumonitis is indicated only in a symptomatic child with hypoxia and consists of oral therapy with corticosteroids to suppress the lymphocytic proliferation [365]. Lymphocytic interstitial pneumonitis has been associated in some studies with a better prognosis than other HIV-related manifestations such as encephalopathy or PCP, with a median survival of 72 months after diagnosis compared with 1 month for encephalopathy and 11 months for PCP [367].

## CARDIOVASCULAR COMPLICATIONS

Cardiovascular abnormalities are seen in more than 50% of HIV-infected adults and have been described in children [368,369]. A progressive left ventricular dilation and an increase in ventricular afterload were shown in a group of 51 children with symptomatic HIV disease but with a normal initial echocardiogram [369]. Clinical manifestations include hepatosplenomegaly, tachypnea, and tachycardia, often with an $S_3$ gallop or another arrhythmia. Postmortem examination is remarkable for biventricular dilation with grossly unremarkable valves and coronary arteries and, less frequently, a pericardial effusion. Cardiomyopathy is more commonly found in children with HIV-related encephalopathy (30%) than in children without this manifestation (2%) [334].

Microscopically, hypertrophy of the myocardium with only rare foci of inflammatory lymphocytic infiltrates is usually present [370,371]. HIV RNA can be shown in only a few cells, probably representing macrophages, monocytes, or endothelial cells, but the distribution does not correlate with the structural damage [372,373].

Another poorly understood phenomenon is the formation of aneurysms of the cerebral and coronary arteries in association with HIV infection [337,374,375]. A child who developed large cerebral aneurysms, leading to hypothalamic dysfunction and neurologic impairment, has been described [376].

## PATHOLOGY OF THE GASTROINTESTINAL TRACT

Dysfunction of the digestive tract is a frequent problem in children with AIDS. In an Italian study of 200 HIV-infected children, Galli and colleagues [377] observed a higher incidence of hepatitis and diarrhea with onset during the first year of life (occurring in 20% to 50% of cases) than at any later time. Commonly encountered pathogens that may cause severe diarrhea are *Cryptosporidium*, *M. avium-intracellulare* complex, *Microsporidium*, *Salmonella*, and *Shigella* [378]. HIV nucleic acids have been found in the feces of children with persistent diarrheal disease [379]. Many HIV-infected children have a gastrointestinal dysfunction owing to disaccharide intolerance, however [379].

Progressive weight loss, anorexia, and sometimes pathogen-negative diarrhea characterize the wasting syndrome often seen in association with HIV disease [380–383]. The cause is unclear, but probably represents a combination of a metabolic imbalance with hypermetabolism, disturbed nitrogen balance, and increased cytokine levels. No specific treatment is available, but individual patients may benefit from appetite stimulants, dietary supplements, or parenteral nutrition [384].

Liver dysfunction resulting from an infection, including cytomegalovirus, Epstein-Barr virus, the hepatitis viruses, *M. avium-intracellulare* complex, or HIV-1, is a common feature and can evolve into a chronic hepatitis or cholangitis [385,386]. *Candida albicans* and the herpesviruses are often the cause of infections of the oral cavity and of esophagitis. Esophagitis in the HIV-infected child does not manifest with typical symptoms or dysphagia, but may be the cause of poor appetite and weight loss. Pancreatitis is a rare complication of HIV infection in children and may occur as a result of opportunistic infections such as cytomegalovirus or as a side effect of therapeutic agents [387,388].

## NEPHROPATHY

Renal disease in children with HIV infection manifests most often as focal glomerulosclerosis or mesangial hyperplasia. In one study, 12 of 155 children between the ages of 7 months and 8 years were found to have proteinuria, and 5 of them developed severe renal failure within 1 year of diagnosis [389,390]. This nephrotic syndrome is often resistant to treatment with corticosteroids, but cyclosporine may induce a remission [391]. IgA nephritis has been observed in a few HIV-infected children and adults,

clinically manifesting as recurrent gross hematuria [392,393]. An infection with cytomegalovirus or treatment with the protease inhibitor indinavir can also cause hematuria [394,395]. Immune complex disease may be involved in the pathogenesis of HIV-related nephropathy.

## PATHOLOGY OF ENDOCRINE ORGANS

Failure to thrive or grow is commonly seen in children with HIV infection. In a study of 35 HIV-positive hemophiliacs, a decrease of more than 15 percentile points in height or weight for age was a predictive marker for children who became symptomatic for AIDS [396–398]. Although a few patients may have some dysregulation of thyroid function or a lack of growth hormone, often no definable endocrine cause is recognizable [399,400]. The exception is a child with adrenal insufficiency, which may be caused by cytomegalovirus infection of the adrenal gland [401]. One child with severe salt craving was described who required therapy with fluorocortisol. In a study of 167 HIV-infected children, Hirschfeld and associates [402] found decreased levels of free thyroxine in 18% and increased thyrotropin or thyroid-binding globulin levels in 30% of children.

## INVOLVEMENT OF LYMPHOID ORGANS AND THYMUS

Thymic abnormalities have been found in 3 of 37 fetuses aborted between 20 and 27 weeks' gestation [403]. Thymic abnormality may represent the initial injury to the lymphoid system. In children with AIDS, the thymus can show precocious involution, with marked depletion of lymphocytes and loss of corticomedullary differentiation, or thymitis, characterized by the presence of lymphoid follicles with germinal centers or a diffuse lymphomononuclear infiltration [404]. Multilocular thymic cysts can occur, often detected as an incidental finding [404]. Lymphadenopathy is common among infected children and adults, and lymphoid organs function as reservoirs for HIV-1 [405–408].

## HEMATOLOGIC PROBLEMS

Anemia is the most common hematologic disorder observed in HIV-infected children, with incidence depending on the severity of HIV disease, the age group, and the use of antiretroviral therapy [409–411]. In a retrospective study of 75 HIV-infected children, 19.7% had anemia at age 6 months, 32.9% at 9 months, and 37.3% at 12 months [412]. Bone marrow aspirate or biopsy specimens may show lymphoid aggregates, some degree of dysplasia, or an ineffective erythropoiesis [413]. Pure red blood cell aplasia from acute or persistent B19 parvovirus infection has been described in some HIV-infected children and adults and should be considered when the red blood cell production rate is less than expected for the degree of anemia [414–416].

A white blood cell count of less than 3000 cells/mm$^3$ has been observed in 26% to 38% of untreated pediatric patients, and neutropenia, defined as an absolute neutrophil count of less than 1500 cells/mm$^3$, has been found in 43% [409–411]. This neutropenia can result from HIV infection, infection with opportunistic pathogens such as *M. avium-intracellulare* complex or cytomegalovirus, or therapy with a myelotoxic drug, including zidovudine.

In the patient population at the National Cancer Institute, a platelet count of less than 50,000 cells/mm$^3$ was found in 19% of the children; thrombocytopenia has also been described in HIV-infected infants [417–419]. Treatment options are similar to those of noninfected children and include intravenous gamma globulins, corticosteroids, and WinRho (anti-D immunoglobulin). Improvement is often best achieved, however, by optimizing the antiretroviral therapy and decreasing the circulating viral load.

Deficiency of vitamin K–dependent factors II, VII, IX, and X is common in HIV-infected children and can result in a coagulopathy that is relatively easy to correct. Also commonly seen are autoimmune phenomena, such as lupus anticoagulants and antiphospholipid or anticardiolipid antibodies [420–422]. Disseminated intravascular coagulopathy has been described as a complication of fulminant infectious conditions, but there are no data to indicate that this complication occurs more frequently in HIV-infected individuals.

## SKIN

Mucocutaneous disease is very common in pediatric HIV infection, but often manifests in an unusual or atypical form [423,424]. The most common lesions with an infectious cause are oral thrush and diaper rash (*C. albicans*), chickenpox (acute or chronic), recurrent shingles (varicella-zoster virus), and molluscum contagiosum [425]. Bacterial infections and a highly contagious form of scabies have also been reported with some frequency. Severe seborrheic dermatitis or a nonspecific, intensely pruritic eczematous dermatitis can pose difficult and frustrating clinical problems, necessitating prolonged therapy. Because of the atypical presentations and wide variety of possible causes, it is often prudent to culture lesions for bacteria or for varicella-zoster virus or to perform a scraping or biopsy. Drug eruptions seem to be more common in HIV-infected patients and can develop into a toxic epidermal necrolysis [423]. Most drug-related rashes resolve after stopping the causative agent, however.

## MALIGNANCIES

Several case reports of malignancies associated with HIV infection in infants and children have been published; however, cancer is the AIDS-defining illness in only 2% of children compared with 14% of adults [426]. The most common cancer in HIV-infected children is non-Hodgkin lymphoma as a systemic disease or as a primary central nervous system tumor [427–429]. Kaposi sarcoma has been described in a few children, including a 6-day-old infant, but is relatively uncommon [430–432]. Leiomyomas and leiomyosarcomas, soft tissue tumors associated with Epstein-Barr virus infection in immunocompromised patients, are increasingly common [433,434].

# MORBIDITY, MORTALITY, AND PROGNOSIS

The natural history of HIV infection in children has changed significantly in the United States and Europe since the introduction of antiretroviral therapy [5,19–25]. As a result of more effective treatment of HIV infection

and associated complications and improved guidelines for prophylaxis of opportunistic infections, major decreases in the morbidity and mortality rates of HIV-infected children and adults have occurred in developed countries [5,19–25]. HIV-infected infants with unknown status or infants not receiving antiretroviral treatment are still at high risk for early and severe morbidity, however, and continue to have a high mortality rate [237,435,436]. Without treatment, the risk of mortality in HIV-infected children living in the United States and Europe is approximately 10% to 20% [5,258]. In contrast, HIV-associated morbidity and mortality are very high in African cohorts; results of a pooled analysis showed that about one third of children with HIV infection die by 1 year of age, and more than half die by age 2 years [31]. Infants with intrauterine or intrapartum acquisition of infection have the fastest disease progression [31].

The clinical course of HIV infection in children differs greatly from infected adults [5]. Studies from developed countries and sub-Saharan Africa indicate that HIV disease often progresses more rapidly in infants than in adults [31,437]. Infants with perinatally acquired HIV-1 infection have widely variable clinical courses and durations of survival. Although the course of HIV infection in children is generally more accelerated than in adults, distinct subgroups are noticeable. Early reports suggest a bimodal disease expression with 20% to 25% of untreated HIV-1–infected infants rapidly progressing to AIDS or death during the 1st year of life, and others having a better prognosis, with some now surviving into young adulthood [237,253,258].

These studies of the natural history of perinatal HIV infection were performed before the routine use of antiretroviral therapy in pregnant women and their infants. In a European study of 392 HIV-infected children, Blanche and colleagues [237] found that 20% of children died or developed an AIDS-defining symptom (CDC category C; see Table 21–3) within the 1st year of life and 4.7% per year thereafter, reaching a cumulative incidence of 36% by 6 years of age. Two thirds of the children alive at 6 years of age had only minor symptoms, and one third had well-preserved $CD4^+$ counts (<25%) despite prior clinical manifestations. Children with HIV infection acquired through a transfusion during the neonatal period tend to have a prolonged asymptomatic period [438].

Clinical and laboratory factors have been evaluated in regard to their prognostic value. Children born to mothers with advanced disease, low $CD4^+$ counts, and high viral load tend to progress more rapidly to category C disease or death, emphasizing the importance of diagnosis and adequate treatment of HIV-infected pregnant women [176,323,439,440]. Early clinical manifestations of HIV infection in the infant, especially development of AIDS-defining conditions such as PCP and HIV encephalopathy or hepatosplenomegaly, has repeatedly been associated with a poor prognosis [253,258,441,442]. In contrast, slow depletion of $CD4^+$ T-lymphocyte count, late onset of clinical symptoms, and occurrence of lymphocytic interstitial pneumonitis are associated with improved survival [253,258].

A high virus copy number in the blood has been shown to be a strong predictor for progression of HIV disease [171,443,444]. Infants with very high HIV RNA copy numbers shortly after birth are presumed to have been infected in utero and tend to have early onset of symptoms [444]. Dickover and associates [444], when calculating HIV-infected infants followed for up to 8 years, found that a 1-log higher HIV-1 RNA copy number at birth increased the relative hazard of developing CDC class A or B symptoms by 40% ($P$ = .004), of developing AIDS by 60% ($P$ = .01), and of the risk of death by 80% ($P$ = .023). The peak HIV-1 RNA copy number during the period of primary viremia was also predictive of progression to AIDS (relative hazard 9.9, 95% CI 1.8% to 541%, $P$ = .008) and death (relative hazard 6.9, 95% CI 1.1% to 43.8%, $P$ = .04) [444].

## PREVENTION

An important goal in the care of HIV-infected individuals is the prevention of further infections and especially the transmission of HIV from mother to infant. Many countries have initiated large educational programs to halt the spread of the epidemic in the heterosexual community. The prevalence of HIV infection is so high in certain populations, especially in developing countries, that a change in behavior results in only a very slow decrease in the number of new infections. Identifying pregnant women who are HIV infected is essential for the potential initiation of combination antiretroviral therapy for maternal health and to prevent mother-to-child transmission of HIV [222,223].

### EXPERIENCE IN PERINATAL HUMAN IMMUNODEFICIENCY VIRUS PREVENTION IN THE UNITED STATES

Major advances have been made in prevention of perinatal transmission of HIV during the last decade in the United States and Europe [6–13]. Perinatal HIV transmission rates has decreased to less than 2% as a result of widespread implementation of routine antenatal HIV testing ("opt-out" approach), use of antiretroviral prophylaxis and HAART, elective cesarean delivery, and avoidance of breast-feeding [15,16]. Efforts to prevent perinatal HIV transmission have been pursued since the discovery of the virus in 1983 [1–4]. In 1985, the CDC issued guidelines recommending that HIV-infected women in the United States should not breast-feed [445]. The success of the Pediatric AIDS Clinical Trials Group (PACTG) 076 protocol in 1994 has had a major impact on the prevention of perinatal transmission of HIV-1 and has resulted in guidelines issued by the CDC [222,223,446,447]. In that landmark study, pregnant HIV-infected women received oral zidovudine starting at 14 to 34 weeks of gestation and intravenous zidovudine during labor and delivery, and the infants were treated with 6 weeks of oral zidovudine during the postpartum period (Table 21–6). This regimen resulted in a 67% reduction in the perinatal transmission rate, from 25% to 8.3% ($P$ = .00006) [446]. It has also been shown that a high maternal plasma concentration of HIV-1 is a risk factor for transmission to the infant [41]. The mechanism of action of zidovudine is not fully understood. In the

**TABLE 21–6** Pediatric AIDS Clinical Trials Group 076 Zidovudine Regimen

| Time of Zidovudine Administration | Route | Regimen |
|---|---|---|
| Antepartum | Oral | 100 mg zidovudine five times daily, initiated at 14-34 wk of gestation and continued throughout pregnancy |
| Intrapartum | Intravenous | During labor and delivery, intravenous administration of zidovudine in a 1-hr initial dose of 2 mg/kg, followed by continuous infusion of 1 mg/kg/hr until delivery |
| Postpartum | Oral | Oral zidovudine to newborn (zidovudine syrup at 2 mg/kg per dose every 6 hr) for the first 6 wk of life, beginning at 8-12 hr after birth; if infant cannot tolerate oral zidovudine, it can be given intravenously at a dosage of 1.5 mg/kg every 6 hr |

*From Centers for Disease Control and Prevention. Public Health Service task force recommendations for the use of antiretroviral drugs in pregnant women infected with HIV-1 for maternal health and for reducing perinatal HIV-1 transmission in the United States. MMWR Morb Mortal Wkly Rep 47:1-31, 1998.*

PACTG 076 study, zidovudine reduced maternal HIV-1 RNA only modestly, and change in maternal HIV-1 RNA levels accounted for only 17% of the reported efficacy of zidovudine [41]. In addition, zidovudine reduced transmission at all levels of maternal HIV-1 RNA levels. The continued efficacy of zidovudine in reducing transmission even in women with low viral loads suggests that preexposure and postexposure prophylaxis of the infant during labor and delivery may be a substantial component of protection [8].

After the publication of PACTG 076 study results in 1994, the CDC issued guidelines that all pregnant women should be offered HIV testing and recommended zidovudine for all pregnant HIV-infected women according to the PACTG regimen [222]. In 1998, the Institute of Medicine released a report recommending universal HIV screening with right of refusal for all pregnant women [448]. In 1999, the U.S. Congress provided target funding for prevention of perinatal HIV infection in states with high prevalence. In 2001, the CDC issued revised HIV counseling and testing guidelines for pregnant women, recommending strategies to reduce barriers to offering antenatal HIV testing to ensure routine HIV testing and offering rapid HIV testing during the labor and delivery period for women with unknown HIV status [449].

In 2003-2006, the CDC reported high uptake of screening of pregnant women using the “opt-out” strategy. In 2006, the CDC expanded the use of the “opt-out” strategy to include routine HIV testing in health care facilities to all patients 13 to 64 years old and all pregnant women as part of the routine panel of antenatal tests, a second HIV test in the third trimester for women living in areas with high incidence of HIV or women at high risk, and rapid testing for women with unknown status at the time of labor and delivery [219]. Widespread implementation of these recommendations and the introduction of combination antiretroviral therapy since the late 1990s has led to a marked decrease in the number of newly HIV-infected infants in industrialized countries [10–13]. In 1992, approximately 2000 infants in the United States acquired perinatal HIV infection, whereas currently less than 200 infants acquire HIV infection [10,18].

Because maternal plasma viral load is a critical predictor of perinatal HIV transmission [43,72–77] the effect of maternal HAART and combination antiretroviral regimens on transmission has been studied in open-label and epidemiologic studies. Combination antiretroviral regimens are more effective for prevention of perinatal HIV transmission than single-drug regimens alone. Investigators from France and Thailand reported that zidovudine and lamivudine prophylaxis is more effective than zidovudine alone in reducing mother-to-child transmission of HIV [450,451].

In the United States, a large multicenter prospective cohort study of 1542 HIV-1–infected, non–breast-feeding pregnant women and their infants (Women and Infant Transmission Study) found that HIV-1 transmission was 20% (95% CI 16.1% to 23.9%) for 396 women with no prenatal antiretroviral therapy, 10.4% (95% CI 8.2% to 12.6%) for 710 women receiving zidovudine monotherapy, 3.8% (95% CI 1.1% to 6.5%) for 186 women receiving dual therapy without protease inhibitors, and 1.2% (95% CI 0 to 2.5%) for 250 women receiving combination antiretroviral therapy with protease inhibitors [16]. Transmission also varied by maternal HIV-1 RNA level at delivery: 1% for less than 400 copies/mL, 5.3% for 400 to 3499 copies/mL, 9.3% for 3500 to 9999 copies/mL, 14.7% for 10,000 to 29,999 copies/mL, and 23.4% for greater than 30,000 copies/mL. The odds of transmission increased 2.4-fold (95% CI 1.7 to 3.5) for every log [10] increase in delivery viral load. In multivariate analyses adjusting for maternal viral load, duration of therapy, and other factors, the odds ratio for transmission for women receiving combination therapy with or without protease inhibitors compared with women receiving zidovudine monotherapy was 0.30 (95% CI 0.09 to 1.02) and 0.27 (95% CI 0.08 to 0.94) [16].

Levels of maternal viral load at delivery and antenatal antiretroviral therapy were independently associated with transmission. The protective effect of therapy increased with the complexity and duration of the regimen, and maternal HAART was associated with the lowest rates of transmission [16].

Current perinatal HIV prevention guidelines issued by the CDC recommend combination antiretroviral therapy with at least three antiretroviral drugs during pregnancy if maternal viral load is 1000 copies/mL or greater (Table 21–7) [223]. In addition, elective cesarean delivery is recommended if maternal viral load is 1000 copies/mL or greater near delivery. Because of the proven benefit of antiretroviral prophylaxis in preventing perinatal HIV-1 transmission in women, including women with viral load less than 1000 copies/mL [74], all HIV-infected women should receive prophylaxis using the PACTG zidovudine regimen alone or combination antiretroviral therapy. Zidovudine monotherapy administered to HIV-infected women with viral load less than 1000 copies/mL has been

**TABLE 21–7** Guidelines for Preventing Perinatal HIV-1 Transmission*

| ***Maternal HIV-1 RNA Level > 1000 copies/mL*** |
|---|
| Combination ART (ideally including zidovudine after first trimester), intravenous zidovudine infusion during labor, followed by oral zidovudine for 6 wk to infant |
| Elective cesarean section if maternal HIV-1 RNA level >1000 copies near delivery |
| ***Maternal HIV-1 RNA Level < 1000 copies/mL*** |
| Zidovudine alone after first trimester (controversial) or combination ART (ideally including zidovudine after first trimester), intravenous zidovudine infusion during labor, followed by oral zidovudine for 6 wk to infant |
| ***HIV-1-Infected Women Who Have Had No ART before Labor*** |
| When woman has not received any therapy during pregnancy, several efficacious intrapartum and postpartum regimens are available |
| Intravenous zidovudine infusion during labor followed by oral zidovudine for 6 wk to infant OR |
| Intravenous zidovudine infusion plus single-dose nevirapine at onset of labor. To reduce the development of nevirapine resistance, add lamivudine during labor and maternal zidovudine/lamivudine for 7 days postpartum. Infant should receive single-dose nevirapine plus zidovudine for 6 weeks. |
| ***HIV-1-Infected Women Who Have Had No ART before or during Labor*** |
| Oral zidovudine should be prescribed to neonate as soon as possible after delivery (preferably within 6-12 hr of birth) and continued for 6 wk |
| Some experts advocate use of postnatal zidovudine regimen in conjunction with other antiretroviral agents |

*ART, antiretroviral therapy.*
**From Centers for Disease Control and Prevention. U.S. Public Health Service task force recommendations for use of antiretroviral drugs in pregnant HIV-infected women for maternal health and interventions to reduce perinatal HIV-1 transmission in the United States. Available at http://aidsinfo.nih.gov/contentfiles/PerinatalGL001020.pdf. 8 July 2008, posting date.*

shown to reduce perinatal HIV transmission to 1% [74]. In addition, no long-term effects on women's health have been noted among U.S. women enrolled in the PACTG 076 trial in terms of disease progression, mortality, viral load, or zidovudine resistance between randomized treatment and placebo arms [452].

When the mother has not received any therapy during pregnancy or during the labor and delivery period because of detection of HIV in the mother or infant after delivery, observational data suggest that administration of oral zidovudine for 6 weeks to the infant started within 24 hours after birth may provide some benefit against transmission [453]. In such instances, other antiretroviral agents could be added to the postnatal zidovudine regimen [220].

The role of elective cesarean section delivery in reducing perinatal HIV-1 transmission was recognized before the advent of combination antiretroviral therapy during pregnancy [91,92]. Data from a large international meta-analysis of 15 prospective cohort studies and a randomized controlled trial from Europe showed that cesarean section performed before labor and rupture of membranes is associated with at least a 50% decrease in the risk of perinatal HIV transmission independent of the use of antiretroviral therapy or zidovudine prophylaxis [91,92]. Both these studies were done before the advent of HAART during pregnancy, and there was no information on maternal serum HIV-1 RNA level. Because the level of maternal serum HIV RNA level is an important predictor of perinatal HIV-1 transmission [43,72–77] it is unclear if elective cesarean section would offer any additional benefit in women successfully treated with HAART who have a very low or undetectable viral load [454].

The risk of postnatal HIV-1 transmission through breast-feeding has been documented [48,49]. In resource-rich countries where infant formulas are safe and readily available, HIV-infected mothers should be advised not to breast-feed their infants [113,455].

Despite significant advances in prevention of maternal-to-child transmission of HIV, approximately 150 HIV-infected infants are born annually in the United States, primarily because of missed prevention opportunities, including inadequate prenatal care, lack of antenatal HIV testing, and clinicians offering prenatal HIV testing only to women they consider high risk [9,456]. Knowledge of HIV status during labor is crucial for providing zidovudine prophylaxis for women who test positive and their infants to prevent perinatal transmission [457]. The Mother-Infant Rapid Intervention at Delivery (MIRIAD) study showed the feasibility of rapid HIV-1 testing of women with unknown HIV status during labor [457]. The MIRIAD study results have important implications for populations in developed countries, but may have a greater impact in sub-Saharan Africa, where approximately 29% of women do not receive prenatal care [458]. Other challenges include preventing new HIV infections in women of childbearing age, especially adolescent girls of minority race or ethnicity, and preventing unplanned pregnancy in adolescent girls [9,456].

## INTERNATIONAL EXPERIENCE IN PERINATAL HUMAN IMMUNODEFICIENCY VIRUS PREVENTION

Although the PACTG 076 regimen is very effective, it is not feasible to implement this intervention in resource-limited countries where 1800 new perinatal infections occur per day [28]. In addition, most transmission occurs late in pregnancy or at the time of delivery [6,47]. Shorter, less expensive regimens that are more applicable to resource-limited countries were studied in trials. The results of major studies on antiretroviral prophylaxis to prevent perinatal HIV transmission in breast-feeding and non–breast-feeding populations are presented in Tables 21–8 and 21–9. Initial studies focused on regimens that were modifications of zidovudine monotherapy.

The efficacy of short-course prophylaxis regimens of zidovudine, started at 36 weeks of gestation with no infant prophylaxis, in reducing perinatal HIV transmission was studied among non–breast-feeding populations in Thailand (see Table 21–8) [459]. Results from this study, performed in Thailand as a collaboration between the Thailand Ministry of Health and the CDC, showed a 50% reduction in perinatal HIV transmission in a non–breast-feeding population [22]. This trial enrolled non–breast-feeding women who were treated with zidovudine

(300 mg twice daily) beginning by 36 weeks of gestation with no infant prophylaxis component. During labor and delivery, the oral dose of maternal zidovudine was increased to 300 mg every 3 hours. The estimated efficacy of this therapy was 51% (decrease from 18.6% transmission rate in placebo group to 9.2% in treated group) [459].

The identical short-course zidovudine antepartum and intrapartum regimen used in Thailand [459], when evaluated in a placebo-controlled trial in Abidjan, Cote d'Ivoire, involving breast-feeding populations, showed an efficacy of 37% reduction in transmission to infants compared with placebo at 3 months of age [460]. Another placebo-controlled trial in West Africa studied a similar antepartum and intrapartum short-course zidovudine prophylaxis regimen with the addition of a 1-week course of zidovudine to mothers during the postpartum period and reported an efficacy of 38% at 6 months of age in predominantly breast-fed infants [461]. An additional week of postpartum maternal zidovudine therapy did not confer any additional benefit over the antepartum and intrapartum zidovudine-alone prophylaxis regimen. A study in Thailand showed that longer duration of zidovudine prophylaxis (starting at 28 weeks of gestation) is more effective than shorter duration regimens (starting at 36 weeks) [462]. In addition, if the duration of the maternal antepartum regimen is short (<4 weeks), longer infant prophylaxis (4 to 6 weeks) is more effective than shorter infant prophylaxis (3 days to 1 week) [460].

The efficacy of antiretroviral regimens in reducing antepartum and intrapartum transmission is diminished over time in breast-feeding populations. Long-term pooled analysis showed an efficacy of 26% by 24 months of age compared with 37% to 38% efficacy noted in infants at 3 months and 6 months of age in this population with long-term breast-feeding [463]. The overall efficacy of short-course zidovudine is less in breast-feeding populations in sub-Saharan Africa than in formula-fed populations [460,461], and the early efficacy seems to diminish with prolonged breast-feeding [463].

When the efficacy of short-course zidovudine was established, studies explored whether combination antiretroviral regimens are more effective than single-drug prophylaxis. Investigators from the United States and France and Thailand evaluated whether combining a second antiretroviral agent such as lamivudine would enhance further the efficacy of short-course zidovudine in reducing transmission in non–breast-feeding populations [464,465]. The French open-label, nonrandomized study assessed the safety of perinatal lamivudine-zidovudine combination prophylaxis in infants and its effects on perinatal transmission of HIV in a non–breast-feeding population [464]. The study enrolled 445 HIV-1–infected pregnant women, who received lamivudine at 32 weeks' gestation through delivery in addition to the standard PACTG 076 zidovudine prophylaxis regimen. Infants received lamivudine for 6 weeks in addition to the standard 6-week course of zidovudine. The transmission rate in the study group was 1.6% compared with 6.8% in a historical control group of HIV-infected mother-infant pairs in France who had received only zidovudine [464].

The Thailand open-label, nonrandomized trial studied the efficacy of lamivudine added to short-course zidovudine prophylaxis. This study enrolled 106 HIV-1–infected pregnant women, and lamivudine and zidovudine were begun at 34 weeks' gestation and given orally during labor. Infants received a 4-week course of zidovudine alone. The transmission rate in the study group was 2.8% compared with 11.7% in a historical control group of HIV-infected women in Thailand who had received only short-course zidovudine [465]. A WHO/UNAIDS multicenter, placebo-controlled trial involving breast-feeding populations in Africa to prevent mother-to-child transmission of HIV by short-course antiretroviral regimen (PETRA trial) showed an efficacy of 63% at 6 weeks for zidovudine and lamivudine given from 36 weeks' gestation, intrapartum, and for 1 week postpartum to mothers and infants; 42% efficacy for intrapartum-postpartum zidovudine and lamivudine; and no efficacy for intrapartum treatment only (see Table 21–9) [466].

When the woman has not received any therapy during pregnancy, several efficacious intrapartum and postpartum regimens are available based on data from several international clinical trials. Shorter antepartum and intrapartum regimens are not as effective for preventing perinatal HIV transmission, however, as regimens that include longer three-part antepartum, intrapartum, and postpartum prophylaxis. In a study in Uganda (HIVNET 012), a single dose of nevirapine given to the mother at onset of labor and a single oral dose of 2 mg/kg given to the infant at 48 to 72 hours of life were safe and reduced perinatal HIV transmission by 47% at 14 to 16 weeks of life and by 41% at 18 months in breast-feeding infants (see Table 21–9) [467,468]. Nevirapine is a very potent non-nucleoside analogue with a long half-life and excellent penetration across the placenta [469]. The single-dose nevirapine regimen is simple, inexpensive, and feasible to implement in resource-limited settings. Another trial conducted in South Africa comparing the efficacy of nevirapine (intrapartum and a single dose postpartum to mothers and to infants) versus zidovudine and lamivudine (intrapartum and for 1 week postpartum to mothers and infants) showed that the risk of infant HIV-1 infection at 8 weeks of age was similar in the two groups (see Table 21–9) [470].

Addition of single-dose nevirapine can significantly improve the efficacy of other short-course antiretroviral regimens [471,472]. Two trials conducted in Thailand (non–breast-feeding women) and West Africa (partly breast-feeding population) showed that addition of single maternal intrapartum and neonatal nevirapine doses to short-course maternal zidovudine (with oral zidovudine during labor and either no infant prophylaxis or 1 week of infant zidovudine prophylaxis) may provide increased efficacy for reducing perinatal HIV-1 transmission compared with short-course maternal zidovudine prophylaxis alone or short-course zidovudine and lamivudine [471,472]. The combined two-drug regimen study from Thailand conducted in a non–breast-feeding population showed equivalent efficacy in reducing perinatal HIV transmission as HAART regimens used in developed countries [471].

In contrast, an international, blinded, placebo-controlled phase 3 trial conducted in non–breast-feeding populations in the United States, Europe, Brazil, and the Bahamas (PACTG 316) found no additional benefit from two

intrapartum and newborn nevirapine doses when women received prenatal care and standard antenatal antiretroviral therapy and elective cesarean section was made available. All neonates in this study received the standard 6-week zidovudine course, and the overall risk of perinatal HIV transmission was very low (1.5%) [473]. In this study, nevirapine resistance developed in 15% of the women who received single-dose intrapartum nevirapine [473,474]; addition of intrapartum and newborn nevirapine doses is not recommended in HIV-infected women who have received HAART during pregnancy [16].

In resource-limited settings, women often present in late labor and do not receive intrapartum antiretroviral prophylaxis in a timely fashion. A study conducted in a breast-feeding population in Malawi evaluated the efficacy of infant antiretroviral prophylaxis when no antepartum or intrapartum maternal antiretroviral therapy was received. This trial compared the efficacy of single-dose infant nevirapine versus single-dose infant nevirapine plus 1-week infant zidovudine; results showed that the combined regimen had a superior efficacy (7.7% transmission) compared with single-dose infant nevirapine alone (12.1% transmission) at 6 to 8 weeks of age [475]. When mothers received intrapartum nevirapine as preexposure prophylaxis, transmission rates were similar, however, for infants who received combined single-dose nevirapine plus zidovudine (6.9%) and for infants who received single-dose nevirapine only (6.5%) [476]. A future clinical trial is currently ongoing in non–breast-fed populations in the United States and Brazil to assess the efficacy of the standard 6-week infant zidovudine regimen when compared with two combination regimens (nevirapine dose at birth and 3 and 7 days of life and 2-week course of lamivudine and nelfinavir) [8].

The WHO recommends a tiered approach for the use of antiretroviral drugs for treatment of HIV-infected women and prevention of perinatal HIV transmission in resource-limited settings [477]. The revised recommendations include provision of triple-drug antiretroviral treatment for HIV-infected pregnant women who are eligible for treatment (CD4 count $<$ 350 cells per cubic millimeter or WHO stage 3 or 4 disease). For pregnant women who are not eligible for HAART or where antiretroviral therapy is unavailable, the WHO recommends a combination antiretroviral prophylaxis regimen, preferably zidovudine from 28 weeks of gestation; zidovudine, lamivudine, and single-dose nevirapine during delivery; and zidovudine and lamivudine for 7 days postpartum to reduce the development of nevirapine resistance. Newborn infants who are breastfeeding should receive daily nevirapine prophylaxis until the cessation of breast-feeding [477]. Provision of antepartum and postpartum maternal triple-drug prophylaxis which is continued until the cessation of breast-feeding is another option for women who do not need HAART for their own health. Although efforts are ongoing to provide more effective regimens, the single-dose nevirapine regimen alone should still be used in settings where it is not feasible to implement more effective regimens or where these regimens are unavailable [477].

Despite the use of simple, efficacious prophylactic antiretroviral regimens worldwide, in resource-limited countries, less than 10% of HIV-infected pregnant women receive antiretroviral drugs to prevent mother-to-child transmission of HIV [28]. There are major barriers to implementation of perinatal HIV prevention programs in resource-poor countries [9,26]. Challenges include weak health care systems, limited resources, no stock of antiretroviral drugs and HIV test kits, lack of integration of perinatal HIV prevention programs into existing maternal-child services, limited prenatal care services, and limited HIV counseling and testing centers [9]. Other challenges include lack of male involvement, issues of disclosure, and lack of family planning services [9,26]. Social, cultural, and gender issues and divergent political agendas compound the dilemma further [9].

Transmission of HIV through breast-feeding is a major public health challenge in settings where replacement feeding is not feasible [48,49,97]. The risks of acquiring HIV infection through breast-feeding may be lower than the risk of death from diarrheal diseases and malnutrition in areas where replacement feeding is unavailable or unsafe. Decision models to determine the optimal choice of interventions to reduce breast-feeding transmission have been proposed [478]. For developing areas of the world, the WHO recommends exclusive breast-feeding through the first 6 months of life, introduce complementary foods thereafter, and continue breast-feeding for the first 6 months of life. Commercial infant formula milk as a replacement feed is acceptable only in countries where replacement feeding is "acceptable, feasible, affordable, sustainable, and safe" [479].

There is an urgent need to make breast-feeding by HIV-1–infected women safer to prevent postnatal transmission of the virus [480]. Innovative strategies have been proposed for prevention of HIV-1 transmission via breast milk in resource-poor settings, including maternal or infant, or both, postpartum antiretroviral prophylaxis for 6 months during breast-feeding; provision of combination antiretroviral therapy during lactation; active (infant vaccines) and passive (antibodies) immunoprophylaxis that boost infant immune responses during the period of breast-feeding; and exclusive breast-feeding with or without early weaning [48,49,117]. Early infant weaning, at or before age 6 months, may be associated with increased risk of morbidity and mortality owing to malnutrition, gastroenteritis, and other infectious diseases [97,480]. More recent observational studies indicate that infant prophylaxis is safe and may reduce transmission of HIV through breast-feeding [480]. International readers should refer to the WHO guidelines for updates regarding recent clinical trials of antiretroviral interventions to reduce postnatal transmission of HIV during breastfeeding [477].

## SAFETY AND TOXICITY OF ANTIRETROVIRAL PROPHYLAXIS

With widespread use of antiretroviral prophylaxis to prevent perinatal HIV transmission in resource-poor countries and the availability of combination antiretroviral therapy for HIV-infected mothers during pregnancy, an increasing number of infants are being exposed to antiretroviral agents in utero and during the postnatal period [33,481]. Animal data have shown that nucleoside

analogues may be carcinogenic and can cause mitochondrial dysfunction [223]. An extensive review of short-term and medium-term data from several studies indicates, however, that antiretroviral therapy during pregnancy has been well tolerated by mothers and infants [33,481]. Except for mild, transient anemia [8], no serious short-term maternal or infant adverse effects have been noted with prophylactic zidovudine regimens [482,483].

A European study reported an association between low birth weight or preterm delivery with the use of combination antiretroviral agents during pregnancy [484]. Data from a large meta-analysis of seven studies performed in the United States found no association, however, between increased rates of low birth weight, preterm delivery, low Apgar scores, or stillbirths and the use of combination antiretroviral therapy [485].

Current data indicate that infants exposed to commonly used antiretroviral agents such as zidovudine, lamivudine, stavudine, nevirapine, and nelfinavir during early pregnancy are no more likely to have a congenital anomaly than infants in the general population [484,486]. The French perinatal cohort study group reported possible mitochondrial abnormalities resulting in fatal outcomes in a large cohort of uninfected infants exposed to zidovudine alone or zidovudine and lamivudine during pregnancy or in the neonatal period [487]. Another study from France suggested a possible association of early febrile seizure with perinatal exposure to nucleoside analogues [488].

In contrast, a retrospective review of 16,000 uninfected U.S. children born to HIV-infected mothers, with and without antiretroviral exposure, failed to identify any deaths related to mitochondrial dysfunction [489]. Short-term to medium-term follow-up data from the European Collaborative Study involving 2414 uninfected children born to HIV-infected mothers and exposed to antiretroviral agents in utero or early life did not show any serious adverse events, including febrile seizures and clinical manifestations suggestive of mitochondrial abnormalities [490]. The long-term outcomes of infants exposed to combination antiretroviral therapy in utero are unknown. Long-term follow-up of all infants born to mothers exposed to antiretroviral therapy is recommended [223].

## ANTIRETROVIRAL RESISTANCE

Emergence of viral resistance is a concern with global use of antiretroviral prophylaxis to prevent perinatal HIV transmission [491]. Nevirapine resistance has been a topic of major interest because the WHO recommends nevirapine-based treatment regimens as the first-line therapy in resource-limited nations [492]. A single gene mutation in HIV-1 reverse transcriptase can confer rapid resistance to commonly used antiretroviral agents such as lamivudine and nevirapine [491]. In an open-label study from France, addition of lamivudine to zidovudine after 32 weeks of gestation was associated with lamivudine resistance (M184V mutation) in 39% of women postpartum [464].

In the HIVNET 012 study, 19% of women exposed to the single intrapartum nevirapine dose acquired nevirapine-resistant mutations (predominantly K103N mutation); however, resistance was transient and no longer detectable 12 to 24 months after delivery [493]. In the same study, nevirapine-induced genotypic resistance was detected in 46% of nevirapine-exposed infants who subsequently became infected, but the mutations faded by 12 months of age [493]. The mutations were different in mothers and infants, and no resistant virus was transmitted from mother to infant. In the absence of continued drug exposure, these resistance mutations fade from detection in women and infants over time, and transmission of nevirapine-resistant virus seems less likely [491]. In a more recent study, nevirapine resistance mutations were detected 10 days after delivery in 32% of women who had received intrapartum nevirapine; women who received intrapartum nevirapine were less likely to have virologic suppression after 6 months of postpartum treatment with a nevirapine-based regimen [494]. The long-term clinical consequences of nevirapine-induced genotypic resistance on future treatment options are unknown and warrant future study [495].

With the use of more sensitive techniques, nevirapine resistance can be found in 60% to 89% of women after early exposure [496–499]. Emergence of nevirapine-resistant HIV-1 in this setting is more common among women who have a high viral load, low $CD4^+$ count, and subtype C and D rather than A [500]. This subset of women should be considered for HAART to improve their own health and to reduce the risk of perinatal and possibly postnatal HIV-1 transmission [491,501]. In contrast, nevirapine resistance is less likely to emerge in healthy women who do not require HAART during pregnancy and could benefit from single-dose nevirapine prophylaxis to prevent perinatal HIV-1 transmission [491,501].

# TREATMENT

## SUPPORTIVE CARE AND GENERAL MANAGEMENT

Optimizing prenatal care, including nutrition, avoidance of drugs and other harmful substances, and recognition and treatment of concurrent infections, is crucial to prevent the premature delivery of infants with low birth weight. The general care of the newborn and infant is not different for infants born to HIV-seropositive mothers, but special attention should be given to the documentation of developmental milestones, frequency and course of infections, and nutritional status.

HIV-infected children are at higher risk for developing vaccine-preventable diseases than HIV-uninfected children. The AAP recommends routine immunizations with some modifications for all HIV-exposed infants, whether they are infected or not [38,124,226]. Similar to other newborns, infants born to HIV-infected mothers should receive hepatitis B vaccinations, but if the mother is positive for hepatitis B surface antigen, the infant should also receive hepatitis immune globulin within 12 hours after birth. Readers are referred to the 2006 edition of the *Red Book* for guidance regarding immunization practices in HIV-infected children [38].

Infants infected with HIV should be vaccinated at the appropriate age with inactivated vaccines (diphtheria, tetanus toxoids, and acellular pertussis; *Haemophilus influenzae* type b; hepatitis B; hepatitis A; and pneumococcal conjugate vaccine) and the influenza vaccine annually.

The current recommendation is that live virus vaccine (oral poliovirus) or live bacterial vaccines (bacillus Calmette-Guérin) should not be given to patients with HIV infection. The exception is measles-mumps-rubella (MMR) vaccine because of the high risk of mortality noted among HIV-infected children who develop wild-type measles, although only children with mild to moderate immunosuppression should have the MMR vaccine [38]. Children may receive the second dose of MMR vaccine 4 weeks after the first dose rather than waiting until school entry.

Varicella-zoster immunization is contraindicated in HIV-infected children and adults with severe immunosuppression. Data regarding varicella vaccine in HIV-infected children are limited, and physicians should examine the potential risks and benefits. The AAP recommends that varicella vaccine should be administered to HIV-infected children 12 months or older in CDC categories N1 and A1 (i.e., asymptomatic or mild signs and symptoms of disease and $CD4^+$ lymphocyte percentage $\geq$15% and no evidence of varicella immunity) [38]. The CDC recommends that two doses of varicella vaccine should be given, with a 3-month interval between doses [502]. Some experts consider varicella vaccination for asymptomatic HIV-infected patients receiving HAART with normal immune function ($CD4^+$ lymphocyte percentage >25%) for more than 6 months, even if they previously exhibited symptoms or had severe immunosuppression (CDC category C) [38]. Household contacts of HIV-infected infants can receive varicella vaccine because transmission of vaccine-type varicella-zoster virus is unusual. More recently, the Advisory Committee on Infectious Diseases has recommended the oral rotavirus vaccine for HIV-infected infants.

Immunization with the conjugated pneumococcal vaccine (PCV7) series is recommended as a four-dose series for infants at 2, 4, 6, and 12 to 15 months of age. PCV7 induces protective antibody responses in infants 2 months of age. Alternatively, children older than 2 years with HIV infection who previously have not received PCV7 should be administered a series of two doses of PCV7 and one dose of the 23-valent polysaccharide pneumococcal vaccine (PPV23) given at an 8-week interval between doses, followed by another dose of PPV23 3 to 5 years after the first dose [38].

Passive immunization of children with HIV infection is recommended in certain circumstances, especially after exposure to measles, varicella, or tetanus. A recommended prophylaxis regimen in HIV-infected infants after exposure to wild-type measles is the administration of intramuscular immunoglobulin (0.5 mL/kg, maximum dose 15 mL) regardless of their measles immunization status. Likewise, HIV-infected children exposed to varicella or shingles should receive intravenous immunoglobulin (IVIG) or specific hyperimmune globulin (if available) within 96 hours after exposure to varicella-zoster virus regardless of their immunization status [38]. Children who have received IVIG within 2 weeks of exposure to measles or varicella do not need additional prophylaxis. Children with HIV infection with tetanus-prone wounds should receive tetanus immune globulin regardless of immunization status.

The monthly administration of IVIG has been studied in asymptomatic and symptomatic children with HIV infection. IVIG has been shown to prevent serious bacterial infections in patients with congenital immunodeficiencies. In a group of children who did not receive any antiretroviral treatment, only children with a $CD4^+$ count of 200 cells/mm$^3$ or greater seemed to benefit from monthly IVIG administration [503]. A study evaluating children receiving antiretroviral therapy did not find a statistically significant difference between children who received IVIG and children treated with placebo (albumin), as long as they were also receiving PCP prophylaxis with TMP-SMX. The current recommendation is to use prophylactic IVIG (400 mg/kg per dose every 28 days) in HIV-infected children with hypogammaglobulinemia (IgG <400 mg/dL) [38]. IVIG should be considered for HIV-infected children who develop recurrent serious infections such as bacteremia, meningitis, or pneumonia during a 1-year period [38].

The evaluation and therapy for infectious complications in HIV-infected children mandate a high level of suspicion for unusual presentations; an aggressive approach to establish the diagnosis; and the use of intravenous antibiotics, at least during the initial days. Chronic and recurrent infections can compromise the nutritional status of the child and influence the neurodevelopmental state. These symptoms are also typical for progressive HIV infection and should be monitored carefully.

The CDC has published guidelines for prevention and treatment of opportunistic infections among HIV-infected infants and children [218,278,504]. Prophylactic measures for the prevention of PCP have been discussed previously. Prophylaxis for *M. tuberculosis* exposure follows the guidelines used for immunocompetent children, but all children born to HIV-infected mothers should have a purified protein derivative test placed at or before 9 to 12 months of age and should be retested every 2 to 3 years [159]. Prophylaxis with clarithromycin or azithromycin for *M. avium-intracellulare* complex infection should be offered to infants younger than 12 months with $CD4^+$ counts less than 750 cells/µL, children 1 to 2 years old with $CD4^+$ counts less than 500 cells/µL, children 2 to 6 years old with $CD4^+$ counts less than 75 µL, and children older than 6 years with $CD4^+$ counts less than 50 cells/µL [218,278,504].

Data are limited regarding the safety of discontinuing prophylaxis in HIV-infected children receiving antiretroviral therapy. Many experts recommend stopping primary prophylaxis for PCP, however, in children older than 1 year receiving HAART and with $CD4^+$ percentage greater than 25%. Other aspects of HIV management include assessment of organ system involvement, development and psychosocial assessments, and intervention [38,504]. A family-centered approach involving a multidisciplinary team to integrate medical, social, and psychosocial support is crucial.

# ANTIRETROVIRAL THERAPY

## Early Treatment

HAART is the standard of care for pediatric HIV infection in the United States and other developed countries to improve growth and development, reduce risk of opportunistic infections and other complications, reduce hospitalizations, and prevent development of encephalopathy [18–25]. HAART has evolved from simple nucleoside reverse transcriptase inhibitor (NRTI) regimens of the 1980s and early 1990s to current complex regimens of NRTI in combination with protease inhibitors or non-nucleoside reverse transcriptase inhibitors (NNRTIs) or both [505]. The introduction of combination antiretroviral therapy has resulted in dramatic reductions in mortality and morbidity by greater than 80% to 90% in children in the United States and Europe [18–25,178].

As knowledge about the dynamics of viral replication and its implications for disease progression and prognosis has evolved, it has become clear that early and aggressive therapy offers the potential benefit of a prolonged asymptomatic period. The consideration of treatment initiation for asymptomatic infants is based on the rationale that infants are at highest risk of rapid disease progression to AIDS or death, even when immune degradation and virus replication are moderately well contained, and that there are no reliable clinical or laboratory markers to distinguish infants who will progress from infants who will not progress [506–509]. Studies have shown that the initiation of combination antiretroviral therapy within the first 3 months of life can result in complete cessation of viral replication and preservation of normal immune function [192,510,511]. Studies suggest that several regimens of antiretroviral therapy are safe, effective, and well tolerated for long periods when started in early infancy [510,512].

## Treatment Recommendations

Panels of experts have developed guidelines for the use of antiretroviral agents in children, adolescents, and adults including pregnant women with HIV infection [513]. Indications for the initiation of antiretroviral therapy include clinical, immunologic, and virologic parameters (Table 21–10). Pediatric HIV experts agree that infected infants with clinical symptoms of HIV disease or with evidence of immune compromise should be treated, but controversy remains regarding treatment of asymptomatic infants with normal immunologic status [506]. A study from a South African clinical trial (Children with HIV Early Antiretroviral Therapy [CHER] study) addressed the critical question of when to begin combination antiretroviral therapy in asymptomatic HIV-1–infected infants who are diagnosed early in life [514]. CHER found that initiation of therapy at less than 12 weeks of age in asymptomatic infants with normal immune function resulted in 76% reduction in mortality and 75% reduction in HIV disease progression compared with waiting to initiate treatment in such infants until they met standard criteria for initiation of therapy [514]. Based on the results of CHER, current U.S. guidelines from the Working Group on Antiretroviral Therapy and Medical Management of HIV-Infected Children recommend initiation of antiretroviral therapy for all HIV-infected infants younger than 12 months regardless of clinical status, $CD4^+$ percentage, or HIV RNA level (see Table 21–10) [513].

The Working Group recommends that treatment should be started for all children older than 12 months with AIDS (clinical category C) or significant symptoms (clinical category C) or most clinical category B conditions, regardless of $CD4^+$ percentage or count or plasma HIV RNA level [513]. Treatment with antiretroviral therapy is also recommended for children older than 12 months who have severe immunosuppression (immune category 3), for children 1 year to younger than 5 years who have $CD4^+$ less than 25% and less than 350 cells/mm$^3$ for children 5 years or older regardless of symptoms or plasma HIV RNA level [513].

Initiation of antiretroviral therapy should be *considered* for children older than 1 year who are asymptomatic or have mild symptoms (clinical category N and A) or moderate clinical symptoms (clinical category B—single episode of serious bacterial infection or lymphoid interstitial pneumonitis), *and* have $CD4^+$ percentage 25% or for children aged 1 year to younger than 5 years 350 cells/mm$^3$ or greater for children 5 years or older associated with plasma HIV RNA level greater than 100,000 copies/mL (see Table 21–10) [513]. Many experts would *defer* treatment in asymptomatic or mildly symptomatic children older than 1 year in situations in which the risk for clinical disease progression is low (e.g., $CD4^+$ percentage ≥25%

**TABLE 21–10** Indications for Initiation of Antiretroviral Therapy

aged 1 to <5 years and ≥350 cell/mm$^3$ for children >5 years and have HIV RNA <100,000 copies/mL for children >5 years) and when other factors (i.e., concern for adherence, safety, and persistence of antiretroviral response) favor postponing treatment [513]. In such cases, the health care provider should monitor virologic, immunologic, and clinical status closely.

## Choice of Initial Antiretroviral Therapy

Monotherapy is no longer considered appropriate treatment for HIV-infected children and adults. The only exception is the use of zidovudine monotherapy in infants with indeterminate HIV status during the first 6 weeks of life as part of the regimen to prevent perinatal transmission. As soon as an infant is proved to be infected while on zidovudine prophylaxis, therapy should be changed to a combination of agents [513]. Because of adverse effects and drug interactions, not all agents can be paired in the regimens [513]. Based on results from data from clinical trials, a recommended three-drug combination provides the best opportunity to preserve immune function and to prevent disease progression. This therapy should include a highly active protease inhibitor plus two NRTIs as the initial therapeutic regimen or two NRTIs and one NNRTI [513].

Suppression of virus to undetectable levels and long-term preservation of immune function are the goals. Resistance testing should be considered before starting antiretroviral therapy in newly diagnosed infants younger than age 12 months, especially if the mother has known or suspected infection with drug-resistant virus [513]. A change in HAART regimen should be considered if there is evidence of disease progression (clinical, immunologic, or virologic), adverse effects related to antiretroviral therapy occur, or a new superior regimen becomes available [513].

## Antiretroviral Drug Classes

As of July 2008, 25 antiretroviral drugs were approved for use in the United States in HIV-infected adolescents and adults; of those, 16 have approved pediatric indications, and 15 are available as a pediatric formulation or capsule [505,509,513]. Therapeutic drugs fall into four major classes based on mechanism of action: nucleoside analogues or NRTIs, NNRTIs, protease inhibitors, and fusion inhibitors [505,509,513]. More detailed information about these agents can be obtained at the U.S. federal AIDS information website (http://aidsinfo.nih.gov/guidelines).

The most pediatric experience with NRTIs is with zidovudine, lamivudine, didanosine, and stavudine. All are available in a liquid formulation. Dual NRTI combinations are the backbone of HAART in children. The combinations of NRTIs with the most data available include zidovudine and lamivudine, zidovudine and didanosine, and stavudine and lamivudine. The zidovudine-lamivudine combination is the most widely used because of its extensive safety data in children [505,513]. Added to this dual NRTI backbone is an NNRTI or a protease inhibitor. The acceptable NNRTIs for pediatric use are nevirapine and efavirenz (approved for children >3 years old); efavirenz is not available in a liquid formulation. Delavirdine is the other available NNRTI, but it is not approved for pediatric use. The one available nucleotide reverse transcriptase inhibitor, tenofovir, is approved only for adult use and is not approved for use in children younger than 18 years [513].

Protease inhibitors recommended for pediatric use are nelfinavir, ritonavir, and lopinavir plus ritonavir. These are available in powder or liquid formulations. Other protease inhibitors available for pediatric use are available in capsule formulation only and include indinavir, saquinavir, and amprenavir. These agents are not recommended, however, because no data are available for long-term tolerance and efficacy of any of these combinations in children. Certain combinations are not recommended because of overlapping toxicities, including zalcitabine and didanosine, zalcitabine and stavudine, and zalcitabine and lamivudine. The combination of stavudine and zidovudine is not recommended because of their antagonism [38,509,513].

The most commonly used antiretroviral agents in newborns and infants—the NRTIs zidovudine, lamivudine, and didanosine; the NNRTI nevirapine; and the protease inhibitors lopinavir-ritonavir combination and ritonavir—are briefly reviewed in Table 21–11. More extensive reviews are available in specific textbooks or the current recommendations from the CDC and the federal guidelines website (http://aidsinfo.nih.gov) [505,513]. Because the standards of care are still evolving, collaboration between the child's primary health care provider and an HIV treatment center is strongly suggested. Whenever possible, children should be enrolled in clinical trials; access and information can be obtained by calling 1-800-TRIALS-A (AIDS Clinical Trials Group [ACTG]), or 301-402-0696 (HIV & AIDS Malignancy Branch, National Cancer Institute).

## Challenges

Treatment of infected infants with combination antiretroviral therapy is complex, and high rates of virologic failure have been noted [515,516]. Many practical difficulties in administering drugs to young children compound the problem further. Challenges include issues of medication compliance to complex and demanding regimens, difficulties in developing pediatric formulations, need for refrigeration (e.g., lopinavir), drugs not palatable (e.g., ritonavir), drugs with short shelf life (e.g., didanosine), immature drug metabolism, and lack of age-specific pharmacokinetic data to guide pediatric dosing [517,518]. Toxicity and development of drug resistance are other serious concerns [519].

Resistance is common when a single-dose nevirapine regimen is used for perinatal HIV prevention [493,520]. In one study, an adverse effect on subsequent treatment response was reported in a few infants who started an NNRTI-containing HAART regimen [520]. The WHO still recommends that children should begin on a nevirapine-based HAART regimen pending further studies [521]. Several promising second-generation agents and new classes of antiretroviral agents are currently being

|---|---|---|---|
| ***Nucleoside Reverse Transcriptase Inhibitors*** | | | |
| Zidovudine | Syrup: 10 mg/mL | *Premature infants*: 1.5 mg/kg body weight (IV) or 2 mg/kg body weight (oral) q12h, increased to q8h at 2 wk of age (neonates ≥30 wk of gestational age) or at 4 wk (neonates <30 wk of gestational age) | *More frequent*: anemia, neutropenia |
| | | *Neonatal/infant dose (<6 wk old)*: 1.5 mg/kg of body weight (IV) q6h or 2 mg/kg of body weight (oral) q6h | *Less frequent*: hepatotoxicity, myopathy |
| | | *Pediatric dose (6 wk to <18 yr old)*: 240 mg/m$^2$ q12h *or* 160 mg/m$^2$ q8h; twice-daily dosing preferred in clinical practice | *Rare*: lactic acidosis, hepatomegaly with steatosis |
| Lamivudine | Solution: 10 mg/mL | *Neonatal/infant dose (infants <30 days old)*: 2 mg/kg body weight q12h | *More frequent*: headache, fatigue, reduced appetite, nausea, diarrhea, rash |
| | | *Pediatric dose*: 4 mg/kg body weight q12h | *Less frequent*: pancreatitis, peripheral neuropathy, anemia, neutropenia, lactic acidosis, hepatomegaly with steatosis |
| Didanosine | Pediatric powder for oral solution: 10 mg/mL | *Premature infants*: no data | *More frequent*: diarrhea, vomiting |
| | | *Neonatal/infant dose (2 wk to 8 mo old)*: 100 mg/m$^2$ q12h | *Less frequent*: peripheral neuropathy, electrolyte abnormalities, lactic acidosis, hepatomegaly with steatosis. Combination of stavudine with didanosine may result in enhanced toxicity (fatal and nonfatal cases of lactic acidosis and pancreatitis) |
| | | *Pediatric dose (>8 mo old)*: 120 mg/m$^2$ q12h | *Rare*: pancreatitis, retinitis |
| Stavudine | Solution: 1 mg/mL | *Neonatal/infant dose (birth to 13 days)*: 0.5 mg/kg q12h | *More frequent*: headache, gastrointestinal upsets, rash, lipoatrophy |
| | | *Pediatric dose (age 14 days up to weight of 30 kg)*: 1 mg/kg of body weight q12h | *Less frequent*: peripheral neuropathy, pancreatitis, lactic acidosis, hepatomegaly with steatosis. Combination of stavudine with didanosine may result in enhanced toxicity (fatal and nonfatal cases of lactic acidosis and pancreatitis) |
| | | | *Rare*: increased liver enzymes, ascending neuromuscular weakness |
| ***Non-nucleoside Reverse Transcriptase Inhibitors*** | | | |
| Nevirapine | Suspension: 10 mg/mL | *Neonatal/infant dose (<14 days old)*: treatment dose not defined | *More frequent*: skin rash including Stevens-Johnson syndrome and toxic epidermal necrolysis, fever, headache, nausea, abnormal liver enzymes |
| | | *Pediatric dose (≥15 days old)*: start treatment with 150 mg/m$^2$ (maximum dose 200 mg) given once daily for the first 14 days. If no rash or adverse effects, 150 mg/m$^2$ given twice daily (maximum 200 mg twice daily); higher dosing (i.e., 200 mg/m$^2$ twice daily, not exceeding total daily dose of 400 mg) may be needed for younger children (≤8 yr old) | *Less frequent*: severe life-threatening hepatotoxicity, hypersensitivity reactions |
| ***Protease Inhibitors*** | | | |
| Ritonavir | Oral solution: 80 mg/mL | *Neonatal/infant dose*: not approved for use in neonates/infants ≤1 mo old | *More frequent*: nausea, vomiting, diarrhea, abdominal pain, anorexia, circumoral paresthesias, lipid abnormalities |
| | | *Pediatric dose (>1 mo old)*: 350-450 mg per m$^2$ body surface area twice daily (maximum dose 600 mg). Dose escalation over several days to reduce gastrointestinal adverse effects | *Less frequent*: fat redistribution, exacerbation of chronic liver disease |
| | | | *Rare*: new-onset diabetes mellitus, hyperglycemia, ketoacidosis, hemolytic anemia, pancreatitis, life-threatening hepatitis, allergic reactions, prolongation of P–R interval and second-degree or third-degree atrioventricular block |
| Lopinavir-ritonavir | Pediatric oral solution: 80 mg lopinavir/20 mg ritonavir per mL) | *Neonatal/infant dose (14 days to 6 mo old)*: 300 mg lopinavir per m$^2$ body surface area/75 mg ritonavir per m$^2$ body surface area, *or* 16 mg lopinavir per kg body weight/4 mg ritonavir per kg body weight twice daily. Because dosage data are unavailable for lopinavir-ritonavir administered with nevirapine in infants <6 mo old, lopinavir-ritonavir should not be administered in combination with nevirapine in these infants | *More frequent*: diarrhea, nausea, vomiting, headache, skin rash in patients receiving other antiretroviral agents, lipid abnormalities |
| | | | *Less frequent*: fat redistribution |
| | | | *Rare*: new-onset diabetes mellitus, hyperglycemia, ketoacidosis, hemolytic anemia, pancreatitis, life-threatening hepatitis cardiac toxicity (heart blocks) in newborns, particularly in preterm infants. |

evaluated in adult clinical trials, but pharmacokinetic and safety data are limited in children [522]. These agents include darunavir (protease inhibitor), maraviroc (CCR5 antagonist), raltegravir (integrase inhibitor), and etravirine (new NNRTI) [505]. Data are insufficient to recommend these agents as initial therapy of children [513].

Access to antiretroviral therapy for HIV-infected children is a major challenge in resource-limited settings [523]. Of the estimated 600,000 children who need HAART in sub-Saharan Africa, less than 5% are receiving treatment [29]. Funding from the WHO, the U.S. President's Emergency Plan for AIDS Relief (PEPFAR), and the Global Funds has resulted in significantly increased access to antiretroviral treatment for adults in resource-limited countries; however, implementation of a pediatric HAART program has been very slow. Barriers to treatment include lack of diagnostic testing for early diagnosis of HIV infection in infants, lack of availability of appropriate pediatric antiretroviral drugs, limited infrastructure and health care personnel, and lack of prioritization and advocacy for pediatric treatment [29].

In developing countries, antiretroviral therapy is initiated, if available, with $CD4^+$ percentage less than 20% for children younger than 18 months and with $CD4^+$ percentage less than 15% for older children. HAART generally is initiated at older ages and with advanced immunosuppression compared with in developed countries [524,525]. More recent studies indicate that good clinical and virologic outcomes can be achieved using combination antiretroviral therapy in HIV-infected children living in sub-Saharan Africa and other resource-limited countries [526–528].

## FUTURE GOALS

Major advances in the understanding, prevention, and treatment of HIV disease have occurred in recent years. Dramatic declines in the number of perinatally HIV-1–infected children have been reported in developed countries because of prompt implementation of strategies to prevent mother-to-child transmission of HIV-1. Better understanding of the interactions between viral load and immunologic status and their implications for prognosis has prompted earlier and more aggressive antiretroviral therapy. The advent of the protease inhibitors and the accelerated approval of antiretroviral drugs for children and adults have broadened the therapeutic armamentarium. Availability of HAART has led to improved survival of HIV-1–infected children into adolescence and adulthood, changing most HIV-1 infections into a chronic rather than a fatal disease.

The most urgent need continues to be the prevention of further spread of HIV infection among adults and from a mother to her unborn child. Almost 2 decades after the description of the clinical syndrome of AIDS, we are still dealing with an ever-growing pandemic, affecting certain minorities, both sexes, and all age groups and social levels, but targeting mainly the developing countries with already limited resources. The staggering demands put on public health systems and their financial resources could easily create tensions regarding the distribution of available funds. Before the widespread use of combination therapy and protease inhibitors, the estimated lifetime cost of hospital-based care for children with HIV infection was $408,307 [529]. Assuming that hospital-based care represents 83% of the total charges, the mean overall lifetime cost would be about $500,000. The cost of current antiretroviral therapy is even higher, and life expectancy is longer, although this is partially offset by fewer hospitalizations. Major efforts are needed to make prevention and therapy for HIV infection feasible and affordable for developing nations because they have the highest numbers of infected people with the fewest financial and organizational resources.

New and different antiretroviral agents are needed because of toxicities and emergence of resistance to provide more effective or even permanent inhibition of viral replication. We need to know the pharmacokinetic properties of drugs when given to the pregnant mother, the neonate, or the very young infant. Progress has been made in the early recognition and prophylaxis of opportunistic infections. As patients with HIV infection survive longer, problems with resistant organisms, multidrug allergies, altered organ function, and long-term side effects of medications emerge and complicate adequate therapy.

Advocacy for children and pregnant women, ensuring equal access to new drugs and providing sound data regarding dosing and potential toxicities, continues to be important. The U.S. Food and Drug Administration (FDA) allows the approval of drugs for use in children based on efficacy data gathered in adults if the disease in children and adults is reasonably similar and if the pharmaceutical companies provide dosing (pharmacokinetic) and safety (toxicity) data from controlled trials performed in an adequate number of children. The treatment and care of HIV-infected children and adults has become increasingly complex, and close collaboration with physicians and centers specialized in their care is highly recommended.

Despite successes in developed countries, many serious challenges remain for resource-limited countries. There is a clear need to bridge the gap in perinatal HIV prevention and treatment programs between resource-rich and resource-limited countries [8,9]. Future efforts must focus on rapid scale-up and sustaining effective, simpler, and low-cost prevention of mother-to-child transmission of HIV programs worldwide and developing innovative strategies to prevent transmission of HIV via breast-feeding [117]. Developing a safe, effective preventive infant HIV vaccine would be an optimal strategy to reduce transmission of HIV via breast-feeding [49,166]. Increased public health and political will is needed to reduce the number of pediatric HIV infections worldwide.

CHAPTER 22

# Chickenpox, Measles, and Mumps

**Anne A. Gershon**

## CHAPTER OUTLINE

The viruses that cause varicella, zoster, measles, and mumps may complicate the management of a mother, fetus, or newborn when maternal infection with one of these agents occurs during pregnancy or at term. In the United States, most women of childbearing years are immune to measles and mumps, and there is little opportunity for exposure to these infections because the current population is highly immunized. These diseases posed more problems during pregnancy during the first half of the 20th century than they do now.

Because a licensed varicella vaccine has routinely been used in the United States since 1995, the incidence of varicella among women of childbearing age has also declined owing to personal and herd immunity with decreased transmission of virus. Varicella-zoster virus (VZV) may still inflict significant fetal damage as the cause of congenital varicella syndrome, especially in locations where the vaccine is not being used. Improved methods for control, including better diagnostic methods, antiviral therapy with acyclovir, passive immunization with varicella-zoster immunoglobulin (VZIG), and use of live-attenuated varicella vaccine, have decreased prenatal and postnatal morbidity from this virus, however. Understanding of this viral infection at the molecular level including clarification of the cause of zoster by studies of viral DNA, RNA, and proteins in latency and study of specific viral glycoproteins and their importance in the immune response have advanced our knowledge and can be expected to lead to further improved therapeutic modalities.

## CHICKENPOX AND ZOSTER

Chickenpox (i.e., varicella) is an acute, highly contagious disease that most commonly occurs in childhood. It is characterized by a generalized exanthem consisting of vesicles that develop in successive crops and that rapidly evolve to pustules, crusts, and scabs. Zoster (i.e., herpes zoster, shingles) occurs in persons who have previously had chickenpox. It is typified by a painful or pruritic (or both) vesicular eruption usually restricted to one or more segmental dermatomes. An abundance of virologic, epidemiologic, and immunologic evidence has been amassed indicating that these two illnesses are caused by the same etiologic agent [1], which was designated VZV. Chickenpox is a manifestation of primary infection with VZV. After the acute infection subsides, VZV, similar to other herpesviruses, persists in a latent form. For VZV, the site of latent infection is in the dorsal root and cranial nerve ganglia and intestinal ganglia where certain early viral genes and proteins are expressed in latency [2–5]. VZV may subsequently be reactivated with expression of all of its genes as immunity wanes with time. The reactivated infection assumes the segmental distribution of the nerve cells in which latent virus resided, giving rise to zoster. A description of the historical recognition of disease caused by VZV follows.

*Varicella* is a modernized Latin word used since at least 1764 and intended to connote a diminutive of the more serious variola (i.e., smallpox) [6]. The etymology of "chicken" in chickenpox is less clear. It may also be a diminutive derived from the French *pois chiche*, or "chick pea," a dwarf species of pea (*Cicer arietinum*) [6]. Other authors doubt this Latin origin and conjecture that the word originated from the farmyard fowl, in which case it has a Teutonic ancestry in the Old English *cicen* and the Middle High German *kuchen* [7]. *Herpes* has been used to designate a malady since 1398 ("this euyll callyd Herpes") [8] and derives from the Greek word meaning "to creep"; *zoster* is the Greek and Latin word meaning

DOI: 10.1016/B978-1-4160-6400-8.00022-5

"girdle" or "belt." Shingles, from the Latin *cingulus* (meaning "girdle"), was also used in the 14th century as *schingles* to describe "icchynge and scabs wett and drye" [8].

# ORGANISM

## Classification and Morphology

VZV (Herpesvirus varicellae) is a member of the herpesvirus family. In addition to a burgeoning number of animal herpesviruses, this group includes seven additional, closely related viruses that infect humans: herpes simplex viruses (HSV) types 1 and 2 (Herpesvirus hominis), cytomegalovirus (CMV), Epstein-Barr virus, and human herpesviruses 6, 7, and 8. Only one antigenic type of VZV has been identified, but molecular studies have revealed some minor differences in VZV that have proved useful for epidemiologic studies [9,10].

Common properties of the family include a DNA genome and enveloped virions exhibiting icosahedral symmetry with a diameter of 180 to 200 nm [1]. Nucleocapsids, which are assembled in the nucleus, have a diameter of about 100 nm and consist of a DNA core surrounded by 162 identical subunits, or capsomeres. Nucleocapsids acquire a temporary envelope at the nuclear membrane; they are transported further via the endoplasmic reticulum to the Golgi, where they receive a final envelope. In cell cultures, virions are packaged in vesicles identified as endosomes, which are acidic [11,12]. Virus particles are released from these structures at the cell surface by exocytosis. Extracellular virions are extremely pleomorphic compared with virions of HSV. This pleomorphism, presumably reflecting injury to the envelope possibly caused by exposure to acid or enzymes in endosomes, is believed to account for the lability and lack of cell-free virus that characterizes VZV in tissue culture and in its spread through the body during varicella infection, and it distinguishes VZV from HSV [11–13]. In vivo, enveloped and well-formed VZV is released from cells of the superficial epidermis (strateum corneum), yielding highly infectious virions capable of airborne spread and with a great degree of communicability [14].

Molecular studies have elucidated some details concerning how latent VZV infection is established, maintained, and reactivated. Latent infection probably comes from virions present in skin during varicella. It is unlikely, however, that complete viral replication occurs in the neuron during establishment of latency because the neuron must survive, and replication would be expected to cause cell death. The replication process of VZV is begun during latent infection, but a block in the cascade of viral gene expression probably occurs. About six viral genes and their protein gene products are expressed in latently infected neurons. These proteins are confined to the cell cytoplasm. It seems that when these proteins are transduced into the nucleus by factors still to be determined, reactivation occurs, with formation of all 70 VZV gene products and synthesis of infectious, enveloped virions in the nerve and skin [4].

## Propagation

VZV grows readily in diploid human fibroblasts such as WI 38 cells, the most commonly used cell type for virus isolation. VZV also can be propagated in certain epithelial cells, such as human embryonic kidney, primary human amnion cells, primary human thyroid cells, and Vero (African green monkey kidney) cells. Similar to CMV, the cytopathic effect of VZV is focal in cell culture because of its cell-associated character, and cytopathic effects develop more slowly (3 to 7 days) than with HSV. Animal models for varicella (guinea pigs) [15] and for zoster (rats) [16] have been described. An in vitro model of latency and reactivation in guinea pig enteric neurons has also been developed and provides a setting in which to study factors that influence latency and reactivation [4].

## Serologic Tests and Antigenic Properties of Varicella-Zoster Virus

Several serologic tests are available to measure antibodies to VZV, including indirect immunofluorescence, often called fluorescent antibody to membrane antigen (FAMA) [17,18]; latex agglutination [19]; enzyme-linked immunosorbent assay (ELISA) [20–23]; radioimmunoassay [24]; immune adherence hemagglutination [25]; neutralization [20,26]; and complement-enhanced neutralization [27]. All of these methods are more sensitive than the complement fixation assay [28]. Data gathered from these assays show that antibody to VZV develops within a few days after the onset of varicella, persists for many years, and is present before the onset of zoster.

Serologic cross-reactions between HSV and VZV have been described [29,30]. HSV and VZV share common antigens, and similar polypeptides and glycoproteins have been identified for both viruses, but cross-protection has not been observed [31–33]. Rare simultaneous infections with one or more human herpesviruses have been reported [34,35]. Elevations in heterologous antibody titers in apparent HSV or VZV infections may result from cross-reactions of the viruses, but also may indicate simultaneous infection by both viruses.

VZV produces at least eight major glycoprotein antigens—B, C, E, H, I, K, L, and M—all of which are on the envelope of the virus and on the surface of infected cells. The glycoproteins and internal antigens, such as the capsid and tegument, stimulate production of neutralizing and other types of antibodies and cellular immunity [36–38]. The most prominent glycoprotein of VZV is glycoprotein E. Antibodies elaborated in varicella and zoster are of the IgG, IgA, and IgM classes [39,40].

# EPIDEMIOLOGY AND TRANSMISSION

Chickenpox ranks as one of the most communicable of human diseases. No extrahuman reservoir of VZV is known. Because the supply of susceptible persons, especially in the era before the urbanization of society, would be rapidly exhausted by so contagious a disease, virus latency may have adaptive evolutionary significance in perpetuating infection. In isolated communities, cases of zoster would be responsible for the reintroduction of VZV and its transmission as varicella to new generations of susceptible individuals [1,41].

## Communicability by Droplets and Contact

Historically, transfer of VZV was believed to occur via respiratory droplets, and epidemiologic evidence suggests that transmission can occur before the onset of rash [42–44]. It is rare, however, to isolate VZV from the pharynx of infected patients. A study using polymerase chain reaction (PCR) methods showed that VZV DNA is present in the nasopharynx of a high percentage of children during the early stages of clinical varicella [45], but PCR does not indicate the presence of infectious virus. In contrast, the vesicular lesions in varicella and zoster are full of infectious VZV that can readily be cultured. In a study of leukemic recipients of live-attenuated varicella vaccine, only individuals with skin lesions as a side effect of varicella vaccination spread vaccine-type virus to varicella-susceptible close contacts [46]. Similarly, the rare instances of transmission of vaccine virus from healthy vaccinees to other susceptible individuals occurred only when the vaccinee had a rash [47]. Cell-free VZV virions are known to be copiously produced in skin lesions and are the type of particle that could be aerosolized and involved in viral transmission. The major source of infectious VZV seems to be the skin, although it is possible that transmission from the respiratory tract can also occur.

Airborne spread of varicella has been documented [48,49], but indirect transfer by fomites has not. VZV DNA has been detected in air samples for many hours in hospitals [50], but the relationship to infectivity of the virus is unclear. Varicella is most contagious at the time of onset of rash and for 1 to 2 days afterward [51], but the period of infectivity probably encompasses 1 to 2 days before the rash is noticed until 5 days after onset of the rash.

## Incubation Period

The usual incubation period for chickenpox is 13 to 17 days (mean 15 days). The range is 10 to 21 days, unless passive immunization has been given, in which case the incubation period may be prolonged [44,52].

## Relationship between Varicella and Zoster

It is amply documented that exposure of susceptible persons to zoster may result in chickenpox. Vesicular fluid from patients with zoster produced chickenpox when inoculated into susceptible children [53,54]. Other studies have confirmed that a similar relationship exists under conditions of natural exposure [55]. Claims to the contrary notwithstanding [56,57], it has not been documented that zoster is acquired from other patients with zoster or chickenpox. Instances that have been reported do not exclude the chance sporadic occurrence of zoster in persons who happen to have been exposed to chickenpox or zoster. It is difficult to reconcile this postulated mode of transmission with current concepts of the pathogenesis of zoster, particularly the strict segmental distribution of lesions and the demonstrated presence of VZV DNA, RNA, and certain viral proteins in ganglia during latency [2,3,58]. Studies have also determined that VZV DNA from zoster isolates is identical to that which caused the primary infection, proving that zoster is caused by reactivation of latent VZV [59–61].

## Transplacental Transmission

In pregnancy, VZV may be transmitted across the placenta, resulting in congenital or neonatal chickenpox [62]. The consequences of transplacental infection are discussed in a later section.

## Incidence and Distribution of Chickenpox

There is worldwide distribution of chickenpox. Because vaccination is now routine for children in the United States, significant changes in the epidemiology of varicella have occurred, with evidence of personal and herd immunity [63]. Before the vaccine era in the United States, which began in 1995 with vaccine licensure, outbreaks of varicella occurred each year without major fluctuations between years [64]. Although the disease was seen in all months, more cases occurred in the winter and early spring. This seasonal variation was attributed primarily to the gathering of children in school, but also may be related to changes in environmental temperature. With introduction of the vaccine, there is less varicella disease occurring in all age groups, and the seasonality of the disease is blurred [63].

Chickenpox is more contagious than mumps, but less so than measles [5,65]. After exposure within households, 61% of susceptible persons of all age groups (without a history of previous disease) developed chickenpox compared with 76% for measles and 31% for mumps [52]. Compared with measles, chickenpox is about 80% as infectious in the household, but only 35% to 65% as infectious in society. The reason probably is that chickenpox requires relatively intimate contact for transmission, such as that occurring in the household, whereas in society, there are more casual contacts. Measles may infect efficiently even through casual contacts [65].

An estimated 4 million cases of chickenpox used to occur annually in the United States. Varicella remains a nonreportable disease, but this is expected to change as more and more vaccine is used, and there are fewer and fewer cases of varicella each year. The disease affects both sexes equally and is most commonly seen in children of early school age. Increasing urbanization was associated with acquisition of the disease at younger ages. In Massachusetts from 1952–1961, 29% of children reported with chickenpox were younger than 4 years old, 62% were 5 to 9 years old, 7% were 10 to 14 years old, and less than 3% were older than 15 years old [66]. Later data also indicated that varicella is primarily a disease of young children [67]. A history of varicella is reported by 70% to 80% of young American adults [66,68]. This compares with histories in the same age group in the prevaccine era of 92% for measles, 45% for mumps, and 31% for rubella. Subclinical varicella is uncommon. Data from family studies indicate that only 8% of adults without a history of varicella develop clinical disease when exposed to their own infected children [69]. The relative importance of faulty memory or past subclinical infection in this secondary attack rate is uncertain.

With the use of sensitive assays for the measurement of antibodies to VZV, less than 25% of adults with no history of chickenpox seem to be susceptible [70]. Based on a population of adults in which 90% are immune, this finding suggests a subclinical attack rate of varicella of approximately 7%.

## Incidence of Chickenpox, Mumps, and Measles in Pregnancy

Only a few studies have addressed the incidence of chickenpox, mumps, and measles during pregnancy. In these studies, two questions are posed. First, of all pregnancies, how many are complicated by measles, mumps, or chickenpox? Second, among all reported cases of those diseases, how many occur in pregnant women? In a prospective study of clinically recognized infections that occurred during 30,059 pregnancies in 1958–1964, approximately 1600 women with presumed measles, varicella, and mumps were identified [71]. Taking into account the many possible inaccuracies in such a study, the minimum frequency per 10,000 pregnancies was 0.6 case for measles, 5 cases for varicella, and 10 cases for mumps. In another study of maternal virus diseases in New York City in 1957–1964, Siegel and Fuerst [72] followed pregnant women: 417 were infected with rubella (50.5%), 150 with chickenpox (18.1%), 128 with mumps (15.5%), and 66 with measles (8%).

The data in these studies are undoubtedly flawed because of lack of proven diagnoses and, more importantly, reflect findings in the prevaccine era and cannot be considered as representative today. Today, measles and mumps are rare in the United States, and varicella is becoming less and less common. In highly immunized populations such as exist in the United States, an even lower incidence of infection during pregnancy is predicted for measles, mumps, and varicella. It is possible that the incidence of varicella in pregnant women in the United States is affected by the influx of varicella-susceptible immigrants from countries with tropical climates. A calculation in 1992 projected an incidence of 7 cases of varicella per 10,000 pregnancies, the same as reported earlier in the prevaccine era [73] Given the success of their vaccines, however, one assumes that varicella, mumps, and measles all are now unusual during pregnancy.

## Incidence and Distribution of Zoster

In contrast to chickenpox, zoster is primarily a disease of adults, especially older adults or immunosuppressed patients. Hope-Simpson [41], describing patients of all ages in a general practice observed during a 16-year period, found an incidence of 3.4 cases per 1000 otherwise healthy people per year.

Adults and children older than 2 years who have zoster usually give a history of a previous attack of varicella; in younger infants, a history of intrauterine exposure to VZV can often be elicited [41]. The latency period between primary infection and zoster is shorter if varicella occurs in prenatal rather than in postnatal life [74]. Chickenpox in the 1st year of life also increases the risk of childhood zoster, with a relative risk roughly between 3 and 21 [75,76]. Possibly, this phenomenon is caused by immaturity of the immune response to chickenpox in young infants, permitting early viral reactivation [77].

After infancy, the incidence of zoster increases progressively with age. The attack rate in octogenarians was 14 times that of children in the series by Hope-Simpson [41]. Second attacks of zoster are unusual; 8 were observed in 192 cases in the previously cited series [41]. Four of those attacks involved the same dermatome as the first attack, suggesting a tendency for reactivation of VZV from the same ganglion cells in which the virus was dormant. Some of these cases might have been caused by reactivation of HSV, however; in one study, HSV was isolated from 13% of a series of 47 immunocompetent patients with clinically diagnosed zoster [78]. Zoster in adults and children occurs with increased frequency in patients with malignant hematopoietic neoplasms (especially Hodgkin disease), patients after organ transplantation, and patients infected with human immunodeficiency virus (HIV) [79–81]. Spinal trauma, irradiation, and corticosteroid therapy may also be precipitating factors. The distribution of lesions in chickenpox, which primarily affects the trunk, head, and neck, is reflected in a proportionately greater representation of these regions in the segmental lesions of zoster [41].

## Incidence of Zoster in Pregnancy

More recent studies on the incidence of zoster in pregnancy are lacking. Brazin and associates [82] projected an incidence of 6000 cases annually in pregnant women, which suggests that gestational zoster might be more common than gestational chickenpox, particularly in the vaccine era. Assuming that there are 3.5 million pregnant women yearly in the United States, this calculates to a rate of 20 cases per 10,000 pregnant women per year. Nevertheless, zoster, similar to varicella, seems to be rare or uncommon in pregnancy. The severity or natural history of zoster does not seem to be worse in pregnant women than in the population at large. Implications of gestational zoster for the fetus are discussed in a subsequent section.

## Nosocomial Chickenpox in the Nursery

The precise risk of horizontal transmission in maternity wards or the newborn nursery after VZV has been introduced is unclear, but based on experience, it is very low. This low risk is in part because maternal immunity plays a role in protection of the infant. About 70% of persons give a history of chickenpox by age 20 years, and still others are immune in the absence of a positive history, so that most mothers and hospital personnel are not at risk. Many hospital workers require proof of immunity to varicella (or vaccination) for employment. Only 5% to 10% of women born in the United States seem to be susceptible to varicella, and more than 75% of women with no history of chickenpox seem to be immune [70,83–86]. The percentage of susceptible women among persons raised in tropical climates is higher, probably because viral spread is impeded by high temperatures and the lack of urbanization [83,87–90].

Because IgG antibodies to VZV cross the placenta [83,91], full-term newborns of immune mothers should be at least partially protected from chickenpox. Using the sensitive FAMA assay to measure antibodies to VZV, in a study of 67 infants during the 1st year of life, 50% still had detectable VZV antibodies by age 5 months [83]. Even in premature infants and infants with low birth weight, antibodies to VZV are likely to be

detectable [92–94]. Nevertheless, perinatal chickenpox has been reported rarely in infants born to women with positive histories of chickenpox [95–99]. In the study by Newman [98], varicella developed in a mother and her infant after exposure to a student midwife with chickenpox. The mother had experienced varicella as a child and had a few remaining skin scars; apparently, she had developed a second attack as an adult. Readett and McGibbon [99] reported two cases of extrauterine infection in neonates whose mothers had histories of chickenpox. After delivery at home, each of these infants was exposed within 24 hours of birth to a sibling with chickenpox and subsequently developed skin lesions when 12 and 14 days old. Their mothers did not develop chickenpox in the perinatal period and were found to have serum-neutralizing antibodies to VZV.

In the literature before 1975, VZV antibody titers were not often reported because sensitive tests for measuring these antibodies were not readily available. Since that time, infection of a few seropositive infants after postnatal exposure to VZV has been documented [95,96]. These infants had mothers with a history of varicella, and the VZV antibody in the infants' blood was transplacentally acquired. In one instance, mild varicella developed in a 2-week-old, 1040-g infant who was seropositive at exposure and was passively immunized with VZIG 72 hours after the exposure [96]. In another study, five infants younger than 2 months old, all of whom were seropositive at exposure, developed varicella in a children's custodial institution [95]. Even when varicella develops in the presence of maternal antibodies, it seems to be modified. Although complete protection of every neonate against chickenpox is not guaranteed by immunity in the mother, protection is the exception rather than the rule.

Horizontal transmission of chickenpox in maternity wards and newborn nurseries is uncommon. In some reports, lack of transmission is difficult to explain. In 1965, Newman [98] reported two cases of varicella that occurred in mothers in the same prenatal ward 18 to 19 days after exposure to the index-infected infant and its mother. One mother developed chickenpox 7 days antepartum, and the other developed the disease 3 days postpartum. Each mother was immediately isolated from the ward, but not from her own infant; neither of the infants developed chickenpox. In all, 139 mothers, excluding the index case, were exposed, and 8 developed infection. Three of 42 staff members also became infected. The index infant was the only neonate infected; all other infants, including those born to the eight infected mothers, remained free of disease. Gershon and coworkers [83] described an outbreak in which a woman developed varicella postpartum and exposed 10 mothers and their infants, 1 antepartum woman, and approximately 25 staff members during a brief period while she was waiting in the hospital corridor. Her infant developed varicella 10 days afterward. About 2 weeks later, three cases of varicella developed in the exposed persons: a hospital employee and a postpartum woman and her infant. Gustafson and colleagues [96] described another mini-outbreak that occurred during a 2-month period in a neonatal intensive care unit in which 29 infants were exposed. Two of these infants, whose mothers gave a history of previous varicella, developed chickenpox after exposure to two hospital employees who had been infected nosocomially.

Other reports largely confirm the low rate of transmissibility of chickenpox in neonates. Freud [100] described an infant who had transplacentally acquired disease and developed lesions on the 2nd day of life. None of the other 17 neonates in the nursery became infected, but the index infant had been isolated immediately, so exposure had been very brief. When transferred to another ward, this same infant transmitted the disease to two older children, who were 4 and 7 years old. Odessky and associates [101] reported three instances of congenital varicella: Two infants were immediately isolated, but the third was not recognized as having chickenpox and exposed other neonates for 4 days. The number at risk is not stated, but no instances of transmission were observed. In a report by Harris [102], 35 infants were exposed to 2 infants with congenital chickenpox for periods of 18 and 10 hours before isolation. None subsequently became infected, possibly because all the mothers had positive histories of chickenpox. In an additional case described by Matseoane and Abler [103], an infant developed transplacentally acquired chickenpox at 9 days of age and exposed 13 other neonates in the nursery for periods of 2 to 10 hours before isolation. Six mothers had a positive history of varicella, three did not, and four did not know. None of the exposed mothers or infants developed chickenpox. Lack of transmission despite hospital exposure to an adult with varicella in neonatal intensive care nurseries was also reported by Wang and associates [94] (32 infants), Lipton and Brunell [104] (22 infants), Patou and coworkers [105] (15 infants), Mendez and associates [92] (16 infants), and Gold and coworkers [106] (29 infants).

One experience in a neonatal intensive care unit in Mississippi is illustrative [107]. After the development of hemorrhagic varicella in a 25-week-gestation infant whose mother had varicella 2 weeks previously, 14 infants in the unit were exposed over several days. None of the infants in isolettes became ill, but four who were in open warming units at exposure developed varicella 10 days later. All had received VZIG, and in each instance, the mother gave a history of varicella. The illnesses were mild with only a few papular skin lesions, but three of the four infants were positive for VZV on immunofluorescence testing of skin scrapings. Each infant with varicella was treated with intravenous acyclovir. The incidence of disease was higher in infants of less than 29 weeks' gestation than in infants of longer gestation.

An extensive epidemic lasting 5 months described by Apert [108] in 1895 is of historical interest. Two infants in a newborn nursery developed chickenpox on January 7 and 8. They were immediately transferred with their mothers to another ward, where they were isolated, but a third infant (second generation of chickenpox) developed disease on January 24 and was likewise isolated with his or her mother. A fourth infant (third generation) developed varicella on February 7, but was not isolated until February 13 because the mother deliberately obscured the fact that the infant had lesions. Subsequently,

a fifth infant (fourth generation) developed chickenpox on February 21. Because the number of infants exposed and the maternal histories of varicella are not stated, the attack rates are unclear. Although this was the last case of chickenpox in the newborn nursery, one of the infected neonates introduced the virus to another ward of 40 to 45 debilitated infants. Before the epidemic was over in May, nine generations of chickenpox separated with mathematical precision by 14 days had occurred. In all, 19 infants (12 <6 months old) were infected along with two mothers.

These experiences with nosocomial chickenpox in the newborn nursery are summarized in Table 22–1. In the 20th century, in reports in which the number of neonates exposed is explicitly stated, 218 exposures resulted in only 8 instances of transmission to infants. Most of the mothers had histories of varicella, although in many the history was unknown. Several factors undoubtedly contribute to the low rate of transmission of disease to neonates, including passive immunity in most; relatively brief exposure compared with the household setting, where 80% to 90% of susceptible persons become clinically infected [41,69]; and relative lack of intimacy of contact in the nursery, particularly for infants in isolettes.

## PATHOGENESIS OF VARICELLA AND ZOSTER

In the usual case of chickenpox, the portal of entry and initial site of virus replication is probably the oropharynx, specifically the tonsil [108a]. Attempts to show this directly have been unrewarding, however. In five patients whose blood, throat secretions, and skin were cultured repeatedly during the prodromal period and after the appearance of cutaneous lesions, VZV was recovered from a throat swab in only one instance and from the blood in none. In contrast, vesicle fluid from these patients yielded VZV in all instances [109]. Attempts to isolate the virus from the blood of six additional patients were positive in only one instance: on the 2nd day of rash in an immunosuppressed host. Other, more extensive searches for VZV in throat secretions of patients with varicella, even during the incubation period, proved essentially negative [110,111]. In one report, VZV was isolated from nasal swabs in 4 of 11 children on days 2 through 4 after onset of the rash. VZV could not be isolated during the incubation period or even during the first day of the rash. It was unclear whether the virus was multiplying in the nasal mucosa [112].

VZV has been isolated from blood obtained from patients with varicella. Ozaki and colleagues [113] cultured blood from seven immunocompetent children;

**TABLE 22–1** Nosocomial Chickenpox Infections in the Nursery

| Year | Case No. | Period Others Exposed after Onset of Rash | Prior History of Varicella in Mothers of Infants Exposed | | | No. Persons Exposed | No. Subsequently Infected |

§*Exposure 1–2 days before rash in index case.*

VZV was isolated a few days before the onset of rash or within 1 day after onset. Asano and coworkers [114] similarly isolated VZV from the blood of 7 of 12 otherwise healthy patients with early varicella. The patients from whom virus could not be isolated had been studied after they had the rash for more than 4 days. Both groups of investigators introduced an additional technical step into the blood culture process that might explain why they were successful in isolating VZV when many others before them had not been. The white blood cells were separated on Ficoll-Hypaque gradients and added to cell cultures. Although there was no evidence of viral growth in these cultures, they were blindly passaged onto new cell cultures. Evidence of growth of VZV was present in these second cultures after the blind passage within 2 to 5 days. Before these studies, VZV had been isolated only from blood obtained from immunocompromised patients with varicella or zoster [110,115,116]. The white blood cell infected with VZV is a mononuclear cell, but it is uncertain whether monocytes or lymphocytes, or both, are involved [113,114]. Experiments in the SCID-hu mouse model have shown that VZV is lymphotropic for human $CD4^+$ and $CD8^+$ T lymphocytes and that human T cells release some infectious virus [117].

Data from PCR studies of patients with varicella have yielded various results. In the study by Koropchak and colleagues [118], performed 24 hours after rash onset in 12 patients, 3.3% of oropharyngeal samples, 67% of mononuclear cells, and 75% of skin vesicles were positive for VZV DNA. In the study by Ozaki and coworkers [119] of pharyngeal secretions of chickenpox patients, 26% were positive during the incubation period, and 90% were positive after clinical onset.

Virus is readily recovered from cutaneous lesions soon after the onset of chickenpox. Isolation of VZV was successful in 23 of 25 cases in which vesicle fluid was cultured within 3 days after the onset of the rash, but was successful in only 1 of 7 specimens collected 4 to 8 days after onset [109]. In contrast, the virus apparently persists longer in vesicles of zoster patients, in whom 7 of 10 specimens collected later than 3 days after onset were positive [104]. PCR is more sensitive than virus culture. In the study by Koropchak and colleagues [118], VZV was recovered from only 21% of skin lesions, but 75% were positive by PCR. In contrast to smallpox, chickenpox is no longer communicable by the time the lesions have crusted and scabbed.

The pathogenesis of chickenpox seems to be as follows: Transmission is probably effected by airborne spread of virus from cutaneous vesicles and to a lesser extent by respiratory droplets from patients with varicella or zoster. After an initial period of virus replication in the oropharynx in the susceptible individual, there is invasion of the local lymph nodes and a primary viremia of low magnitude, delivering virus to the viscera [120]. After several more days of virus multiplication, a secondary viremia of greater magnitude occurs, resulting in widespread cutaneous dissemination of virus and rash. Data in SCID-hu mouse model alternatively suggest that VZV is targeted to the skin early in varicella and is initially controlled to a great extent by innate immunity [120a]. Cropping of the vesicles is thought to represent several viremic phases. In the body, the virus spreads by cell-to-cell contact; viremia also is cell associated. Enveloped, cell-free infectious VZV is present, however, in the vesicular skin vesicles. Crusting and scabbing of the vesicles and pustules occur as host defense mechanisms, particularly as various forms of cell-mediated immunity become active. Latency is achieved from the cell-free VZV particles in the skin that are in proximity to sensory nerve endings.

The pathogenesis of zoster differs from that of varicella. Before development of zoster, latent VZV begins to reactivate and multiply in the sensory ganglion (or ganglia) because of unknown local factors [2]. The virus travels down the axon to the skin supplied by that nerve. Development of a localized rash occurs if there is a deficiency in cell-mediated immunity to VZV [121–124]. This compromise in cell-mediated immunity may be obvious, as in patients who have had transplantation, therapy for malignant disease, or HIV infection [125], or, presumably, it may be transient, as in healthy persons who develop zoster for no apparent reason. In immunosuppressed patients, a viremic phase with zoster has been documented occasionally [126,127], and this probably happens after skin involvement has occurred, especially if there continues to be an inadequate immune response to VZV after the virus has reached the skin. The clinical manifestation of this viremia is disseminated zoster, in which vesicular lesions develop outside the original dermatome. A viremic phase in pregnant patients with disseminated zoster has not been documented, but it seems logical to assume that viremia would be a prerequisite for dissemination.

# PATHOLOGY

## Cutaneous Lesions

Histologic changes in the skin leading to the formation of vesicles are essentially identical for chickenpox, zoster, and HSV infection. The hallmark of each is the presence of multinucleated giant cells and intranuclear inclusions, changes that are not found in the vesicular lesions caused by vaccinia virus and coxsackieviruses. The lesion is primarily localized in the epidermis, where ballooning degeneration of cells in the deeper layers is accompanied by intercellular edema. As edema progresses, the cornified layers are separated from the more basal layers to form a delicate vesicle with a thin roof. An exudate consisting primarily of mononuclear cells is seen in the dermis, but the characteristic nuclear changes of epithelial cells are absent in this region.

The predominant cells in vesicular lesions are polymorphonuclear leukocytes. These cells may play a role in generating interferon in vesicular lesions, which may be important in recovery from the disease [128]. In vitro data also suggest that the polymorphonuclear leukocyte plays a role in host defense against VZV, possibly by mediating antibody-dependent cell-mediated cytotoxicity [129–131].

## Visceral Lesions in the Fetus and Placenta

Few reports describe the appearance of the placenta in cases of congenital chickenpox with or without survival. Garcia [132] observed grossly visible necrotic lesions of

the placenta in a case of chickenpox occurring in the 4th month of pregnancy that resulted in spontaneous abortion. Microscopically, central areas of necrosis were surrounded by epithelioid cells and rare giant cells of the foreign body type, giving a granulomatous appearance. Some decidual cells had typical intranuclear inclusions.

Descriptions of the pathology of visceral lesions in fetal or neonatal chickenpox are restricted to autopsies in fatal cases [132–137]. Grossly, the lesions are small, punctate, and white or yellow and resemble miliary tuberculosis. Microscopically, their appearance resembles the lesions of the placenta: central necrotic areas, often resembling fibrinoid necrosis, surrounded by a few epithelioid cells and a scant infiltrate of mononuclear cells. Intranuclear inclusions are present. The skin, lungs, and liver are uniformly involved (Table 22–2) [132]. In the case described by Garcia [132], the cortical, subependymal, and basilar structures of the cerebrum were totally destroyed and accompanied by extensive calcification. Although a search for *Toxoplasma* was negative, serologic data to rule out dual infection are lacking in the report. The gross and microscopic lesions of fatal perinatal chickenpox resemble lesions of disseminated HSV infection, including a preference for the liver and adrenal gland, but the provided data suggest that involvement of the brain is more common in neonatal HSV infection than it is in fatal neonatal chickenpox. A neonate with fatal hemorrhagic varicella with pneumonia and hepatitis is shown in Figure 22–1.

## Visceral Lesions in the Mother

In fatal cases of chickenpox in pregnant women, maternal death is usually caused by pulmonary involvement. The pathologic course of chickenpox pneumonia in pregnant women is identical to the course in nonpregnant women and in children [138,139]. Interstitial pneumonitis may follow a peribronchiolar distribution of disease. Intranuclear inclusions may be found in alveolar lining cells, macrophages, capillary endothelium, and tracheobronchial mucosa. Necrotic foci may be accompanied by hemorrhage, and hyaline membranes lining the alveoli are often prominent.

**FIGURE 22–1 Congenital hemorrhagic varicella complicated by pneumonia and hepatitis.** The mother of this infant developed varicella a few days before delivery. Zoster immunoglobulin was unavailable at that time. *Inset* shows section of liver with intranuclear inclusion bodies obtained at autopsy.

**TABLE 22–2** Frequency of Gross and Microscopic Lesions in Seven Autopsied Cases of Fetal and Neonatal Chickenpox

| Organ | No. Cases/No. Examined (%) | References |
|---|---|---|
| Skin | 7/7 (100) | [132–137] |
| Lungs | 7/7 (100) | [132–137] |

**Not well documented; possibility of concomitant toxoplasmosis not definitely excluded.*

## Zoster

The pathologic picture of cutaneous lesions in zoster is indistinguishable from chickenpox lesions. The dorsal root ganglion of the affected dermatome exhibits a mononuclear inflammatory infiltrate. There may also be necrosis of ganglion cells and demyelination of the corresponding axon. There are no descriptions of these lesions in pregnant women or in neonates specifically.

# CLINICAL MANIFESTATIONS

## Chickenpox Rash

After an incubation period of usually 13 to 17 days [41,66], chickenpox is heralded by the approximately simultaneous occurrence of fever and rash. In adults, the exanthem is often preceded by a prodromal fever and constitutional symptoms lasting 2 or 3 days [7]. Occasionally, one or more isolated vesicles may precede a generalized

exanthem by 1 or 2 days. The rash is characteristically centripetal, beginning on the face or scalp and spreading rapidly to the trunk, but with relative sparing of the extremities. The lesions begin as red macules, but progress quickly to vesicles and crusts. Itching is the rule. There is a tendency for new lesions to occur in crops. In contrast to smallpox, all stages of lesions—vesicles, pustules, and scabs—may occur simultaneously in the same anatomic region. New crops often continue to appear over a 2- to 5-day period. Lesions may be more numerous in skin folds or in the diaper area. The total number of vesicles varies from only two or three in very mild cases, especially in infants, to thousands of lesions that border on confluence, especially in adults [7]. In many cases, one or two mucosal lesions may occur in the mouth or, less commonly, on the vulva. Occasionally, the lesions may be bullous or hemorrhagic. Residual scarring is exceptional. Constitutional symptoms tend to be mild even in the presence of an extensive exanthem.

## Complications of Chickenpox

The most common complication is secondary bacterial infection, usually caused by group A β-hemolytic streptococci or staphylococci. Skin infections may lead to severe sequelae, such as toxic shock syndrome and necrotizing fasciitis [140–148]. Central nervous system complications, which are uncommon, include encephalitis, cerebellar ataxia, aseptic meningitis, and myelitis [149,150]. Glomerulonephritis [151,152], myocarditis [153,154], and arthritis [155,156] have also been reported.

## Chickenpox in Immunocompromised Children

It is widely appreciated that varicella may be severe and even fatal in children with an underlying malignancy, children with congenital deficits in cellular immunity, children receiving high doses of corticosteroids for any reason [157], and children with underlying infection with HIV and acquired immunodeficiency syndrome (AIDS) [81,158]. Historically, children with leukemia had a mortality rate approaching 10% if untreated [159] and sometimes developed what has been called progressive varicella. Instead of developing new vesicular lesions for several days, they continued to have fever and new lesions for 2 weeks after the onset of illness. Frequently, their skin lesions become hemorrhagic, large, and umbilicated. Varicella pneumonia often ensued and was a major factor contributing to the death of a child. It is believed that this abnormal response to VZV represents a failure of the normal cell-mediated immunity response to eliminate the virus [159]. The cell-mediated immunity response to VZV includes antibody-dependent cell-mediated cytotoxicity, natural killer cells, and cytotoxic T cells including CD4 and CD8 cells [36,129–131,160–162]. Today, in the vaccine era, severe or fatal pneumonia in immunocompromised children has become rare or unusual.

## Chickenpox Pneumonia

Primary varicella pneumonia is a dreaded complication of chickenpox and is responsible for most fatalities. It is most common in immunocompromised patients, in adults, and in most fatal cases of neonatal chickenpox [132–134,163], but it is rarely seen in otherwise healthy children. It has been suggested that the incidence is about 15% in adults and that 90% of cases have occurred in persons older than 19 years [163,164]. The true incidence is difficult to determine because chest radiographs are not performed in most cases of chickenpox, and extensive radiographic evidence of disease may be present when pulmonary symptoms are only minimal. In male military recruits with varicella, virtually all of whom had been hospitalized and had chest radiographs, radiographic evidence of pneumonia was found in 16.3% of 110 cases [165].

Two reviews of chickenpox pneumonia in adults outline the major features [139,166]. The onset of pneumonia usually occurs in 2 to 4 days, but sometimes occurs 10 days after the appearance of the exanthem. Fever and cough are present in 87% to 100% of cases, and dyspnea occurs in 70% to 80%. Other symptoms and signs include cyanosis (42% to 55%), rales (55%), hemoptysis (35% to 38%), and chest pain (21%). Radiographic changes seem to correlate best with the severity of the rash rather than with the physical examination of the lungs. The radiograph typically reveals a diffuse nodular or miliary pattern, most pronounced in the perihilar regions. The radiographic appearance changes rapidly. The white blood cell count ranges from 5000 to 20,000 cells/mm$^3$ and is of little help in differentiating viral from secondary bacterial pneumonia. Pneumonia is usually self-limiting, and recovery is temporally correlated with clearing of skin lesions. The fatality rate has been variously estimated at 10% to 30%, but it probably approximates the lower of these values if immunocompromised hosts are excluded [139,166]. Blood gas analyses and pulmonary function tests indicate a significant diffusion defect that may persist in some cases for months after clinical recovery [167]. The introduction of antiviral chemotherapy has greatly improved the outcome in this disease.

## Maternal Effects of Chickenpox

Reports from the mid-20th century suggested that when chickenpox occurred during pregnancy, it was a highly lethal disease. Deaths usually resulted from varicella pneumonia, in some cases accompanied by glomerulitis and renal failure or myocarditis, occurring after the 4th month of gestation [168,169]. Harris and Rhoades [170] reviewed the literature to 1963 and found a reported mortality of 41% for 17 pregnant women with chickenpox pneumonia compared with 11% for 236 nonpregnant adults with chickenpox pneumonia. Other reports question, however, whether varicella, especially in the absence of pneumonia, is more serious in pregnant women than in the adult population at large [136,171,172]. Because most cases of gestational varicella with an uncomplicated course are undoubtedly not reported, the denominator of the case-fatality ratio is unknown. In a prospective study of 150 cases of chickenpox in pregnancy in 1966, only one maternal death related to chickenpox pneumonia was recorded [173].

In a very large, collaborative, prospective study published in 2002, there were no fatalities in 347 consecutive

pregnant women with varicella, although 18 (5.2%) had radiologic evidence of pneumonia [174,175]. Although the data did not reach statistical significance in this study, it seems striking that 16 (89%) of 18 reported cases of pneumonia occurred in women who developed varicella after the 16th week of pregnancy.

Table 22–3 adds data from subsequent case reports of gestational varicella, with and without pneumonia, and reports of perinatal varicella in which the outcome in the mother is described to a review of the literature on varicella pneumonia in pregnancy before 1964 [170]. Among 545 cases of chickenpox in pregnant women, there were 16 deaths (3%). All of the deaths occurred among the 75 women who had chickenpox pneumonia (21% fatality rate for pneumonia). Deaths occurred in 1 (<1%) of 166 women whose disease occurred during the first trimester, 4 (2%) of 168 women whose disease occurred during the second trimester, and 11 (5%) of 208 women whose disease occurred during the third trimester. No deaths occurred among eight women who were exposed to chickenpox in late pregnancy, but did not develop an exanthem until the first few days postpartum.

It remains uncertain whether chickenpox pneumonia has a graver prognosis when it occurs during pregnancy. There is no definitive evidence that chickenpox in the absence of pneumonia is a more serious illness in pregnant women than in other adults; however, the risk of developing pneumonia may be increased after the 16th week of pregnancy. It seems likely that older mortality information on varicella in pregnancy reflected the pre–antiviral therapy era and was biased by selective reporting of fatal cases.

Some patients with varicella during pregnancy who were treated with acyclovir have been reported [172,174–188]. These reports suggest that acyclovir has improved the outcome of this complication of varicella, although controlled studies have not been performed. Although various dosages have been used, the standard dosage of 30 mg/kg/day given intravenously would seem appropriate for treatment of pregnant women with varicella pneumonia. Congenital abnormalities from administration of acyclovir to women during pregnancy have not been observed [189,190].

Controlled studies of the value of corticosteroids in pregnant women with varicella pneumonia have not been performed. Several reports indicate that 2 of 6 pregnant women treated with corticosteroids died, whereas 8 of 17 pregnant women given supportive therapy without corticosteroids died [170,191–194]. It seems that administration of an antiviral drug is of greater importance than administration of corticosteroids. Passive immunization

may be administered to seronegative women after close exposure to VZV to attempt to modify the infection; although uncertain, this approach may prevent fetal infection [195–197]. In a study from 1994, among 97 women who developed varicella after passive immunization with VZIG, there were no observed cases of congenital varicella syndrome [196]. About two abnormal infants could be expected in a series of this magnitude, but the number of women followed is too low to achieve statistical significance.

## Effects of Gestational Varicella on the Fetus

### Chromosomal Aberrations

Available data on chromosomal aberrations are often difficult to interpret, particularly in the absence of controls, which is often the case. VZV can induce chromosomal abnormalities in vitro and in vivo. When human diploid fibroblasts were infected with the virus, a high proportion of cells observed were in metaphase arrest, as if they were under the influence of colchicine [198]. The incidence of chromatid and chromosomal breaks ranged from 26% to 45% 24 hours after infection compared with 2% for control cultures. In the acute phase of chickenpox, up to the 5th day of rash, peripheral blood leukocytes show a 17% to 28% incidence of chromosomal breaks compared with 6% in controls, but 1 month after infection, these abnormalities disappeared [199]. A single case report suggested the possibility that chromosomal damage may be more lasting when chickenpox is acquired in utero. A boy with bird-headed dwarfism, born to a mother who contracted chickenpox in the 6th month of pregnancy, had a 26% incidence of chromosomal breakage in peripheral blood leukocytes when he was examined at 2 years of age [200]. Chromosomal analyses in four infants with congenital varicella syndrome, whose mothers had chickenpox at the 8th, 14th, 16th, and 20th week of gestation, were reported as normal [201–204].

Information on chromosomal aberrations in infants who have no congenital anomalies and are the offspring of mothers with gestational varicella is lacking. Further concern about the possibility of persistent chromosomal abnormalities after intrauterine exposure to VZV is suggested by a prospective survey of deaths among children born in England and Wales from 1950–1952 whose mothers had chickenpox in pregnancy. Two deaths, both from acute leukemia, were reported among the offspring of 270 women; the two children developed acute leukemia at the ages of 3 and 4 years after intrauterine exposure at 25 and 23 weeks of gestation [205]. In the absence of confirmation, it remains questionable whether exposure to chickenpox in utero is a risk factor for leukemia or other malignancies.

### Abortion and Prematurity

Several studies have addressed the question of whether gestational chickenpox and other viral diseases result in an increased incidence of spontaneous abortion or prematurity. In a retrospective study in 1948, only 4 cases of chickenpox were identified among 26,353 pregnant women [206]. No stillbirths occurred in these cases. Prospective studies have tended to confirm that maternal chickenpox during pregnancy is not associated with a significant excess of prematurity [173] or fetal death [207]. Among 826 virus-infected pregnant subjects observed in New York City from 1957–1964, 150 women with chickenpox were followed to term. After exclusion of fetal deaths and multiple births, 5 of 135 live-born infants were found to have birth weights of less than 2500 g. This incidence of prematurity was lower than in the control group of non–virus-infected pregnant women (Table 22–4). Similarly, in the study by Paryani and Arvin [208], premature delivery occurred in 2 (5%) of 42 pregnancies, with delivery at 31 and 35 weeks of gestation.

In a prospective study involving 194 women with gestational varicella and 194 control women, the rate of spontaneous abortion was 3% and 7% in the first 20 weeks [209]. In the large prospective series of Enders and associates [196] of 1330 women in England and Germany who developed varicella, 36 (3%) experienced spontaneous abortions after varicella in the first 16 weeks. In the prospective study of Pastuszak and coworkers [210] involving 106 women with varicella in the first 20 weeks of pregnancy, there were more premature births (14.3%) among women with varicella than among controls (5.6%; $P = .05$). There is no question, however, that the congenital varicella syndrome is associated with low birth weight. Approximately one third of reported cases of the syndrome have been premature, had low birth weight, or were small for gestational age.

**TABLE 22–4** Frequency of Low Birth Weight among Infants Born to Mothers with Selected Viral Infections during Pregnancy

| | Virus-Infected Group | | | Control Group* | | |

[†]*Low birth weight was defined as <2500 g.*

*Modified from data of Siegel M, Fuerst HT. Low birth weight and maternal virus diseases: a prospective study of rubella, measles, mumps, chickenpox, and hepatitis. JAMA 197:88, 1966.*

An accurate assessment of the incidence of fetal mortality after maternal chickenpox is difficult to obtain. Fetal wastage is probably underreported, in part because some spontaneous abortions occur before prenatal care is sought. In the prospective study of maternal viral diseases in New York City referred to earlier [207], nine fetal deaths were observed among 144 instances of maternal chickenpox. Five fetal deaths occurred among 32 pregnancies in the first trimester, four among 60 second-trimester pregnancies, and none among 52 third-trimester pregnancies (Table 22–5). These deaths do not represent significant increases in fetal wastage associated with chickenpox infection compared with control groups in which no maternal viral infection occurred. There was a significant excess of fetal deaths only for mumps, and these occurred primarily in the first trimester. Only three of the nine fetal deaths associated with maternal chickenpox occurred within 2 weeks of the onset of the mother's illness, and two of these were in the first trimester. Two additional deaths occurred 2 to 4 weeks after the onset of maternal chickenpox, two occurred 5 to 9 weeks after the onset of maternal illness, and two occurred 10 or more weeks after the onset of maternal illness. The absence of a close temporal relationship between most fetal deaths and maternal disease provides further support for the concept that maternal chickenpox during pregnancy does not commonly result in fetal mortality.

Although the incidence of fetal death is not increased by maternal varicella, fetal deaths have been associated with maternal varicella. Deaths in utero may result from direct invasion of the fetus by VZV [132,196,211–213] or from the presumed toxic effects of high fever, anoxia, or metabolic changes caused by maternal disease [207]. The precise mechanisms of these toxic effects have not been elucidated. When maternal disease is unusually severe, particularly in cases of chickenpox pneumonia, fetal death may also result from premature onset of labor or death in utero caused by maternal death.*

### Congenital Malformations

For many years, there was uncertainty about whether gestational varicella led to a symptomatic congenital infection. Intensive investigation from the mid-1970s until the end of the 20th century led to the recognition that VZV can cause fetal malformations. Two types of investigations were done to determine whether chickenpox during pregnancy leads to a congenital syndrome. The first investigations were retrospective analyses or case reports describing specific anomalies that occurred in the offspring of mothers who had gestational varicella. These reports were necessarily highly selective and did not define the incidence of such anomalies. They consistently described a syndrome of skin scarring, eye and brain damage, and limb hypoplasia, however, that might follow intrauterine varicella.

The second type of analysis consisted of prospective studies of pregnant women followed throughout pregnancy and afterward. The problem was to delineate the coincidence of two events, each of which is itself uncommon—gestational chickenpox and congenital malformations—to determine the magnitude of risk to the fetus. Siegel [72], despite an 8-year observation period encompassing approximately 190,000 pregnancies annually in New York City, was able to identify only four malformations among infants born to 135 mothers who had chickenpox during pregnancy compared with five malformations among 146 matched controls. The follow-up period was 5 years and included psychomotor and audiometric tests. Chickenpox occurred during the first trimester in only 27 of the pregnancies complicated by chickenpox, and of these, 2 (7.4%) were associated with congenital anomalies compared with anomalies in 3 (3.4%) of 87 pregnancies in the control population.

The largest single prospective series is that of Enders and associates [196]. In a joint prospective study in Germany and the United Kingdom from 1980–1993, Enders and associates [196] followed 1373 women with varicella and 366 with zoster during pregnancy. Of the women with varicella, 1285 continued to term, and 9 had defects attributed to congenital varicella syndrome. The incidence was 2 (0.4%) of 472 for infections between 0 and 12 weeks and 7 (2%) of 351 for infections between 13 and 20 weeks. In a collaborative prospective study in the United States, 347 women with gestational varicella were reported, and adequate follow-up of their infants was available in 231 [175]. In this cohort, there was one case (0.4%) of the congenital syndrome and two cases of fetal death, including one case of hydrops. If these cases are included, the rate of congenital varicella was 1.3%. The mother of the one child with the syndrome had varicella at 24 weeks; the child had skin, eye, and central nervous system involvement.

*References [136,170,177,191,192,212].

That congenital varicella syndrome is a reality is now widely appreciated. It has become possible to make a tissue diagnosis of congenital varicella syndrome only more recently because affected infants do not chronically shed virus as is seen in congenital infections with rubella virus and CMV [196,211,213–215]. Congenital varicella syndrome may be prevented in the future by widespread use of varicella vaccine, analogous to the situation for congenital rubella.

The constellation of developmental abnormalities described in individual case reports of infants born to mothers who had varicella in early pregnancy and in prospective series is sufficiently distinctive to indicate that VZV is a teratogen. In 1947, LaForet and Lynch [216] described an infant with multiple congenital anomalies after maternal chickenpox in early pregnancy. The infant had hypoplasia of the entire right lower extremity, talipes equinovarus, and absent deep tendon reflexes on the right. Cerebral cortical atrophy, cerebellar aplasia, chorioretinitis, right torticollis, insufficiency of the anal and vesical sphincters, and cicatricial cutaneous lesions of the left lower extremity were present. The syndrome then seemed to be all but forgotten until 1974, when Srabstein and coworkers [217] rekindled interest in the subject by reporting another case and reviewed the literature, concluding that although the virus could not be isolated from the infants, congenital varicella syndrome typically consisted of some combination of cicatricial skin lesions, ocular abnormalities, limb deformities, mental retardation, and early death after maternal varicella in early pregnancy (Figs. 22–2 to 22–4). Numerous additional reports in the literature of the syndrome, encompassing more than 100 cases, indicate there is a wide spectrum of manifestations (Table 22–6).*

Although at one time it was thought that congenital varicella syndrome occurred after maternal VZV infection in the first trimester of pregnancy, current evaluation of the data indicates that cases also occur in the second trimester. Of 82 cases for which data are available, 32 (39%) occurred after maternal varicella that developed before the 13th week, 47 (59%) occurred after maternal varicella that developed between weeks 13 and 26, and 1 (1%) [247] occurred after maternal varicella that developed during the 28th week. The average gestation when maternal varicella occurred was 15 weeks. Only six cases occurring after maternal zoster have been reported [248,249,278,279,284]; not all of these are well documented virologically. Four occurred after maternal zoster in the first trimester, one followed zoster in the second trimester [278], and one followed zoster in the third trimester [284]. Of 109 reported affected infants, 103 (95%) cases followed maternal varicella, and 6 (5%) followed maternal zoster (disseminated in one instance).

Scars of the skin, usually cicatricial lesions, are the most prominent stigmata, although a few patients have had no rash at all [265,268,269,285]. Eye abnormalities (i.e., chorioretinitis, microphthalmia, Horner syndrome, cataract, and nystagmus) and neurologic damage are almost as common; other features include a hypoplastic limb, prematurity, and early death. The features of the syndrome are summarized in Table 22–6.

Cutaneous scars were usually observed overlying a hypoplastic limb, but also have been seen in the contralateral limb [216]. Characteristically, the skin scars are cicatricial, depressed, and pigmented and often have a zigzag configuration. Such scars are thought to be the result of zoster that occurred before birth. In some patients, large areas of scarred skin have required skin grafting [229,237]. In other patients, the rash was bullous [236] or consisted of multiple, scattered, depressed, white scars [240,244,257]. In one infant, healing zoster was present at the T11 dermatome at birth; there was also spinal cord atrophy at the same level and aganglionosis of the intestine [256].

Ocular abnormalities include chorioretinitis, Horner syndrome or anisocoria, microphthalmia, cataract, and

*References [74,191,196,201–206,208–283].

Ocular pathology of the congenital varicella syndrome. Arch Ophthalmol 95:2034, 1977.)*

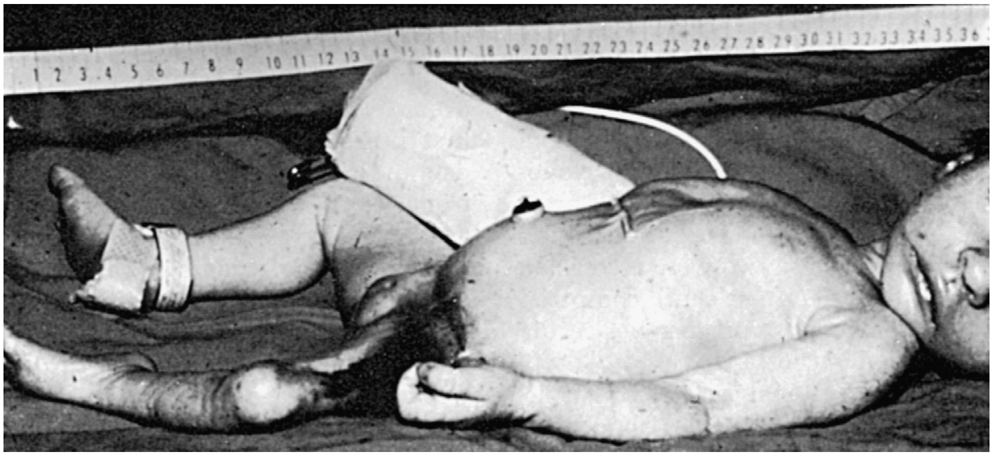

**FIGURE 22–3 This infant, whose mother had varicella during the 13th to 15th weeks of pregnancy, had bilateral microphthalmia with cataracts and an atrophic left leg.** The infant died of bronchopneumonia at age 6½ months. *(From Srabstein JC, et al. Is there a congenital varicella syndrome? J Pediatr 84:239, 1974.)*

**FIGURE 22–4 A child, whose mother had varicella during the 16th week of pregnancy, had atrophy of the left orbit, with blindness that required cosmetic enucleation.** Severe chorioretinitis occurred in the right eye. Except for blindness, the child developed normally. She died of pneumonia when approximately 4 years old. *(Adapted from Frey HM, Bialkin G, Gershon A. Congenital varicella: case report of a serologically proved long-term survivor. Pediatrics 59:110, 1977.)*

nystagmus.* Rarely, major abnormalities were confined to the eye. There was no apparent effect of timing of maternal varicella during gestation; the times of infection varied from 9 to 23 weeks in these infants. Figure 22–2 is a photograph showing retinal involvement in one of these patients [240,251].

Neurologic involvement is about as common as skin and eye abnormalities in infants with congenital varicella syndrome. Patients with cerebral cortical atrophy, diffuse brain involvement, or mental retardation (frequently accompanied by abnormal electroencephalograms and seizures or myoclonic jerks) have been described [216,217,224–226,259]. In a few patients, cerebrospinal fluid findings were normal [74,217,226,253]; in others, there were increased numbers of leukocytes or protein levels [216,223,225]. Bulbar palsy is suspected to result in dysphagia and bouts of aspiration pneumonia in some of these children.* Deep tendon reflexes were reported as normal in one infant [225] and diminished to absent in six,† and they were in some cases accompanied by sensory deficits [74,217,222,226,253]. Electromyography in some patients revealed a denervation pattern with loss of motor units [217,226,227,249,253]. A biopsy specimen in one instance showed replacement of muscle bundles by fat [217]. At least five children with vocal cord paralysis have been reported [259,267,270–272].

**TABLE 22–6** Reported Symptoms and Signs in Infants with Congenital Varicella Syndrome, 1947–2002

| **Symptom** | **Estimated Incidence (%)** |
|---|---|
| Skin lesions (cicatricial scars, skin loss) | 60–70 |
| Ocular abnormalities (chorioretinitis, Horner syndrome, anisocoria, microphthalmia, cataract, nystagmus) | 60 |
| Neurologic abnormalities (cortical atrophy, mental retardation, microcephaly, seizures, dysphagia, limb paresis) | 60 |
| Abnormal limbs (hypoplasia, equinovarus, abnormal or absent digits) | 50 |
| Prematurity, low birth weight | 35 |

†References [203,204,216,217,221,222].

Abnormalities of the limbs can be extremely dramatic in presentation and are seen in about half of affected infants. The most common limb abnormality, which first called attention to this congenital syndrome, is hypoplasia of a limb, most commonly unilateral involvement of a leg or arm (see Table 22–6). Hypoplasia or absence of digits has also been observed [216,218,221,222,225–227]. Talipes equinovarus or a calcaneovalgus deformity has also occurred.* This complex of abnormalities in the limbs, including the bony abnormalities, is probably attributable to a neuropathy caused by direct viral invasion of the ganglia and spinal cord [268].

About one fourth of these infants died within the first 14 months of life. One infant with the obvious syndrome was stillborn [213]. In one infant who died at 6 months, autopsy revealed a necrotizing encephalitis with various degrees of gliosis and inflammatory infiltrates. Focal calcification was observed in white and gray matter of the cerebrum, brainstem, and cerebellum. Atrophy of the anterior columns of the spinal cord and scarring in the ganglion corresponding to the distribution of the skin lesions and an atrophic limb were also present. No inclusion bodies were identified [217]. Among infants with a hypoplastic limb, 40% had evidence of mental retardation or died early. The presence of a hypoplastic limb on an ultrasound examination suggests a poor outcome.

About one third of affected infants were premature or had low birth weight for their gestational ages, and about 10% had various abnormalities of the gastrointestinal tract, including reflux, duodenal stenosis, jejunal dilation, microcolon, atresia of the sigmoid colon, and sphincter malfunction.* A similar percentage had abnormalities of the urinary tract, often caused by poor or absent bladder sphincter function.† Involvement of the cervical or lumbar spinal cord and the autonomic nervous system is thought to account for the observed hypoplasia or aplasia of limbs and digits, motor and sensory defects, decrease or absence of deep tendon reflexes, Horner syndrome, and gastrointestinal and urinary tract abnormalities [280].

Figures 22–3 and 22–4 depict two children with stigmata of congenital varicella syndrome. One has severe [217] and one has relatively mild involvement [240,251].

### Zoster after Congenital Varicella Syndrome

Of children with congenital varicella syndrome, 15% develop clinical zoster in infancy or early childhood, almost all in the 1st year of life.* This finding is of particular interest because cell-mediated immunity to VZV in 2 of 10 of children with the syndrome has been reported to be absent as determined by lymphocyte transformation [202,208]. In the series by Enders and associates [196] of 1291 live births (without congenital varicella syndrome), of whom conservatively perhaps 25% were infected with VZV (the attack rate could be as high as 50%), the rate of zoster in childhood was 3%. Zoster seems to be more common in children with congenital varicella syndrome than in infants who were infected with VZV in utero, but were asymptomatic at birth.

### Diagnosis of Congenital Varicella Syndrome

During the neonatal period or infancy, attempts to isolate VZV from the skin, cerebrospinal fluid, eye, and other tissues in infants with developmental defects were negative.* Although rubella virus and CMV are commonly isolated from young infants affected by these viruses, failure to isolate VZV in these cases is probably explained by the fact that the period of viral replication occurred during early gestation, and no replicating virus persisted by the time of birth. In children who developed zoster at an early age, it has been possible to isolate VZV from the rash [206,227,252]. In seven infants who died, autopsy results showed apparent dissemination of VZV with varicella-like involvement of the lungs, liver, spleen, adrenals, or pancreas [202–204,210,226–229].

Total IgM concentrations in the serum or cord blood of six infants were measured [201,217,226,238–240]. In three instances, the levels were clearly increased, with values of 48 to 100 mg/dL found when the infants were 1.5 to 6 weeks old. Specific VZV antibodies in the IgM fraction were not detected in seven cases in which they were sought [208,226,240,246,280], but they were detectable in six other cases [196,202,203,230,238]. In one of these cases, VZV IgM was detected prenatally by obtaining blood by cordocentesis [280]. In most infants, a decline of antibodies in the serum was observed, a finding compatible with a fetal or a maternal origin. In 10 instances, persistence of or an increase in antibodies in the infant supported a presumption of intrauterine infection.*

It has been possible to document some reported cases of congenital varicella syndrome, but not all of them, because antibody titers may be inconclusive even in children with the apparent full-blown and distinctive constellation of abnormalities. Some children were diagnosed even before it was possible to measure antibody titers to VZV. The development of zoster at an early age can be interpreted as substantiating VZV infection in utero. Although many of the cases reported as congenital varicella syndrome lack proof, it has been possible to show that some infants with characteristic stigmata were infected in utero with VZV, although an active, chronic infection does not exist. Modern molecular methods such as PCR and in situ hybridization have been useful for proving congenital varicella syndrome in a few reported infants and will undoubtedly be used to prove future cases [196,211,213–215,259]. In the future, it is expected that these will become the methods of choice rather than antibody testing. It is also predicted that with widespread use of varicella vaccine, the incidence of this unusual cause of congenital disease will become rare.

### Fetal Malformations and Management of Pregnant Women with Varicella-Zoster Virus Infection

In the 1990s, the incidence of fetal malformations after maternal VZV infection was clarified. Varicella is a significantly greater threat than zoster; 95% of reported cases of congenital varicella syndrome have followed maternal chickenpox. In the series by Enders and associates [196] of 366 women with zoster in pregnancy, there were no cases of congenital varicella syndrome. This outcome is not unexpected because zoster is probably less likely to be accompanied by a viremia than is varicella; many fetuses may escape VZV infection from maternal zoster. Because zoster is a secondary infection, residual maternal immunity to VZV may at least partially protect the fetus from damage, analogous to that seen when congenital CMV infection is caused by reactivation rather than primary CMV infection [285]. As with CMV infection, however, it is possible, although rare, for fetal stigmata to follow secondary maternal infection.

The time at which maternal VZV infection occurs during gestation also influences whether the infant is likely to be severely damaged. Infection during the first and early second trimesters seems to be the most critical. Most reported cases of congenital varicella syndrome have occurred when the onset of maternal infection was before the 20th week of pregnancy. Only seven infants with some of the stigmata have been recorded as the result of maternal varicella after the 20th week [175,211, 245–247,255,284]. When maternal varicella occurs after the 20th week, the infant may be infected, but usually the only evidence is a positive VZV antibody titer when the infant is older than 1 year and, in some cases, development of zoster at an early age.

Eleven prospective studies of the incidence of congenital varicella syndrome have been published. Data from these studies are presented in Table 22–7. There are 14 cases of congenital varicella syndrome in 858 (1.6%) women who developed varicella in the first 20 weeks of pregnancy. If the entire gestational period is considered, 2245 women who had varicella during pregnancy were delivered of live-born infants; the overall incidence of congenital varicella syndrome was 0.6%. These data indicate that the risk for development of congenital varicella syndrome is mostly confined to the first 20 weeks of pregnancy, and the risk after maternal varicella in the first 20 weeks of pregnancy is extremely low, on the order of 1% to 2%. Weeks 7 to 20 are the time of the greatest risk [196]. The tendency to develop overwhelming forms of VZV infection in the fetus indicates the increased ability of VZV to multiply in fetal tissues, which is similar to that of other viruses such as rubella virus and CMV.

Counseling of pregnant women who have acquired varicella during pregnancy can be very difficult. Because the congenital syndrome is rare, termination of pregnancy is not routinely recommended, in contrast to recommendations for gestational rubella. When the syndrome does occur, however, it is likely to be severe. It would be helpful if prenatal diagnoses were available, but diagnostic attempts such as measurement of maternal antibody titers and amniocentesis have not proved useful. Although blood may be obtained by cordocentesis for antibody testing, the presence of fetal VZV IgM does not mean that the infant has congenital varicella syndrome, but only that infection with VZV has occurred. Similarly, PCR may identify an infected fetus, but not one with malformations [283,286].

**TABLE 22–7** Incidence of Congenital Varicella Syndrome: Results of Prospective Studies 1960–1997

| | Incidence of Syndrome | |
|---|---|---|
| **Year** | **First Trimester/ First 20 Weeks** | **Total Gestation** |
| 1960 [508] | 0/70 | 0/288 |
| 1973 [72] | 2/27 | 2/135 |
| 1984 [231] | 0/23 | |

| *Total reported* | 13/858 (1.6%) | 14/2245 (0.6%) |

Ultrasonography has been used successfully to identify the following fetal abnormalities after maternal varicella: hydrocephalus 12 weeks later [202]; clubfeet and hydrocephalus 13 weeks later [233]; a large, bullous skin lesion originally believed to be a meningocele 15 weeks later [236]; calcifications in the liver and other organs 9, 15, and 18 weeks later [214,234,261]; a hypoplastic limb and clubfoot 11 and 16 weeks later [196,214]; and a lacuna of the skull 25 weeks later [230]. Successful use of ultrasound as a diagnostic tool to identify this syndrome prenatally has also been reported in cases with evidence of widespread infection [273–276]. Three published reports indicate, however, that ultrasound is not infallible. In two infants, ultrasound scans were normal 3 weeks after maternal varicella, but the fetuses were later diagnosed as having congenital varicella syndrome [203,233]. One infant was diagnosed with liver calcifications by ultrasonography at 27 weeks and a positive PCR for VZV; his mother had varicella at 12.5 weeks. At birth, no obvious anomalies were present, and the infant did well except for development of zoster at age 8 months [283]. Even defects detected by ultrasonography must be interpreted with some caution.

Because about 40% of reported patients with a hypoplastic limb also sustained brain damage or died in early infancy, the presence of a limb abnormality on ultrasound seems to suggest a poor overall prognosis for the fetus. Two women were reported to have terminated their pregnancies after the diagnosis of congenital varicella syndrome was made based on abnormal limbs on ultrasound scan. At autopsy, the fetuses were found to be severely affected [196,283]. Because abnormalities may not be detected by ultrasound immediately after maternal

varicella, by the time any is noticed, it may be too late to consider interruption of pregnancy, depending on the time of onset of maternal varicella.

Although congenital varicella syndrome varies in severity, most cases are severe. It would be helpful if maternal infection could be identified and appropriate management initiated as early as possible. It is unknown whether administration of VZIG or acyclovir to a pregnant woman can prevent her fetus from developing congenital varicella syndrome. In the study by Enders and associates [196], there were no cases of the congenital syndrome in 97 women who were given VZIG on exposure; it is unknown how many of these women were in the first 20 weeks of pregnancy.

## Perinatal Chickenpox

Perinatal chickenpox includes disease that is acquired postnatally by droplet infection and that is transplacentally transmitted or congenital. Chickenpox is considered to be transplacentally transmitted when it occurs within 10 days of birth.

### *Postnatally Acquired Chickenpox*

Postnatally acquired chickenpox, which begins 10 to 28 days after birth, is generally mild [287]. The experiences with nosocomial chickenpox infections in the newborn nursery that were described in a previous section further corroborate the benign nature of the disease and the fact that transmission to neonates in this environment is inefficient and rarely reaches epidemic proportions.

Deaths among neonates caused by postnatally acquired disease are rare, but some data indicate an appreciably higher incidence of complications or deaths in neonates than in older children [96,101–103,108,287,288]. Preblud and associates [287] found that of 92 reported deaths caused by varicella from 1968–1978 in children younger than 1 year, only 5 occurred in newborns (8 hours to 19 days old). Although mortality was increased by a factor of 4 for infants younger than 1 year compared with older children, there was a low calculated death rate for varicella throughout childhood (8 in 100,000 patients if <1 year and 2 in 100,000 patients 1 to 14 years old) [287]. One 15-day-old infant with severe disseminated chickenpox born to a woman who developed varicella 7 days after delivery has been described [288]. The child survived; acyclovir was administered for 10 days. The only other report in the English literature of severe postnatally acquired varicella in an infant younger than 1 month is that of Gustafson and colleagues [96]. The term infant with Turner syndrome was exposed to varicella when 7 days old, developed more than 200 vesicles, and died of pneumonia; however, the role of VZV in this infant's death was unclear because no autopsy was performed.

### *Congenital Chickenpox: Maternal Infection Near Term*

Congenital chickenpox is not inevitable when maternal chickenpox occurs in the 21 days preceding parturition. In only 8 (24%) of 34 reported cases of maternal disease with onset during this period did chickenpox develop in the neonate within the first 10 days of life [98,136,171,173]. An identical attack rate of 24% for congenital varicella after the occurrence of maternal varicella within 17 days preceding delivery was arrived at by Meyers [289], who reviewed many cases in the literature and 14 examples reported to the U.S. Centers for Disease Control and Prevention (CDC) in 1972–1973. Attack rates on the order of 50% were reported, however, in two studies on the efficacy of passive immunization to prevent severe neonatal varicella [290,291]. In Meyers' study [289], there was no statistically significant relationship between day of onset of the rash in the mother and subsequent attack rates of congenital varicella. Seven of 22 neonates born to mothers whose rash appeared less than 5 days antepartum ultimately developed congenital chickenpox, whereas 4 of 24 infants born to mothers whose rash began 5 to 14 days antepartum had congenital disease [289]. These data indicate that the attack rate in congenital varicella (25% to 50%) is lower than after household exposure to VZV (80% to 90%) and suggest that blood-borne transmission may be less efficient than transmission by the skin and respiratory routes.

The incubation period in congenital varicella, defined as the interval between the onset of rash in the mother and onset in the fetus or neonate, is usually 9 to 15 days [292]. This interval is slightly shorter than the normal postnatal incubation period, possibly because fetal tissues are more susceptible to VZV than more mature tissues. Rarely, presumably when fetal infection is caused by the primary maternal viremia, the exanthem appears in the mother and neonate within 3 days of each other [101] or even simultaneously [292]. The average incubation period in 36 cases reported in the literature was 11 days, with a maximum of 16 days. In only three instances was the incubation period less than 6 days [289].

In contrast to postnatally acquired neonatal chickenpox, congenital chickenpox can be associated with significant mortality. Severe cases clinically resemble varicella in the immunocompromised host. An infant who died of hemorrhagic varicella with pulmonary and liver involvement is shown in Figure 22–1. The spectrum of illness also includes extremely mild infections with only a handful of vesicles. Erlich and coworkers [133] first observed that infants born with the rash or who had an early onset of rash survived, whereas infants who died had a relatively late onset of rash. It was hypothesized that for neonates with early onset, maternal illness had occurred long enough before parturition to allow antibodies to be elaborated by the mother and to cross the placenta. Subsequent reports offer strong confirmation of these observations. There were no deaths among 22 infants with congenital chickenpox (reviewed by Meyers [289] whose onset of rash occurred between birth and 4 days of age. In contrast, 4 (21%) of 19 neonates in whom the rash began when they were 5 to 10 days old died (Table 22–8) [289]. These four deaths occurred among 13 neonates (31%) whose mothers' exanthems developed within 4 days before birth, but no deaths were observed among 23 neonates with congenital chickenpox whose mothers developed a rash 5 or more days before birth.

Further support for the protective or modifying effect of maternal antibody has come from measurements of

**TABLE 22–8** Deaths from Congenital Varicella in Relation to Date of Onset of Rash in Mother or Neonate

| Onset | Neonatal Deaths | Neonatal Cases | % |
|---|---|---|---|
| Day of onset of rash in neonate | | | |
| 0–4 | 0 | 22 | 0 |
| 5–10 | 4 | 19 | 21 |
| Onset of maternal rash, days antepartum | | | |
| ≥5 | 0 | 23 | 0 |
| 0–4 | 4 | 13 | 31 |

*Data from Meyers JD. Congenital varicella in term infants: risk reconsidered. J Infect Dis 129:215, 1974; with permission from the University of Chicago.*

placental transfer of IgG to VZV [91]. When varicella occurred more than 1 week before delivery, complement-fixing antibody titers in maternal and cord blood were similar. In contrast, when infection occurred 3 to 5 days before delivery, maternal antibody was present at parturition, and antibodies to VZV in the neonate were absent or at least eightfold lower. These data suggest that a lag of several days occurs before IgG antibodies to VZV cross the placenta and equilibrate with the fetal circulation. The development of mild congenital varicella in the presence of placentally transferred maternal antibody has also been shown using the more sensitive FAMA test [62]. The neonate may be at risk for developing severe varicella because the immune system is immature, as has been shown by Kohl [293] with regard to host defense against HSV.

## Zoster in Neonates and Older Children

The most characteristic feature of zoster is the localization of the rash. It is nearly always unilateral, does not cross the midline, and is typically limited to an area of skin served by one to three sensory ganglia. In children, prodromes of malaise, fever, headache, and nausea may be observed. Pain and paresthesias in the involved dermatome may precede the exanthem by 4 or 5 days. Involvement of the dermatomes of the head, neck, and trunk is more common than involvement of the extremities, a distribution that also reflects the density of lesions in chickenpox [41]. Erythematous papules give rise to grouped vesicles, which progress to pustules in 2 to 4 days. New crops of vesicles may keep appearing for 1 week. Pain may be associated with the exanthem and usually abates as the skin lesions scab; in elderly adults, severe and incapacitating neuralgia of the involved nerve may persist for months. Cutaneous dissemination of vesicles to sites distant from the involved dermatome is observed uncommonly and is more frequent in compromised hosts, such as patients with lymphoma or immunologic deficiencies.

Zoster occurs as host defense mechanisms against VZV wane in a person who has previously experienced chickenpox. Because immunity is relatively durable, this hypothesis presumes that zoster occurs predominantly in older persons and is rare in neonates. Among 192 patients with zoster in a general practice, the attack rate increased progressively with age [41]. Only six patients were younger than 10 years; the youngest was 2 years old. In two reported series describing zoster in a total of 22 children, only two cases occurred in children younger than 2 years old [171,294]. These reports confirm the rarity of zoster among infants. When zoster occurs in children who have not previously had chickenpox, there is often a history of intrauterine exposure to VZV. In these reports, the mothers contracted chickenpox during gestation, but gave birth to normal infants who, without ever developing chickenpox despite frequent childhood exposure, developed typical zoster at a young age, many in the first few months of life [74,260,295–299]. In most of these infants, the course of zoster was benign. One infant developed a second attack of zoster when 10 months old; the first occurred when the infant was 4 months old [295].

Although there are six reports of zoster during the neonatal period [300–305], it is doubtful whether any of these cases diagnosed on clinical grounds is an authentic example of zoster. HSV may produce a vesicular exanthem in the newborn that appears to have a dermatomal distribution. Virus isolation (or demonstration of VZV DNA or antigen from skin lesions) is required before a diagnosis of zoster can be accepted. Serologic studies are not useful in differentiating these diseases.

# DIAGNOSIS AND DIFFERENTIAL DIAGNOSIS

## Chickenpox

In a neonate with a widespread, generalized vesicular exanthem and a history of recent maternal varicella or postnatal exposure, a diagnosis of chickenpox can usually be made with confidence on clinical grounds alone. Greater difficulty is encountered when lesions are few, or when there is no history of exposure.

### *Diagnostic Techniques*

If laboratory diagnosis is required, it is best accomplished by showing VZV antigen or DNA in skin lesions or isolating virus from vesicular fluid. VZV antigen may be shown by using immunofluorescence, employing a monoclonal antibody to VZV that is conjugated to fluorescein and is commercially available [306–308]. For virus isolation, fluid should be promptly inoculated onto tissue cultures because VZV is labile. PCR has proved extremely sensitive and accurate for diagnosis of VZV infections [118,309–315]. In situ hybridization is also a useful diagnostic technique [215,316,317].

VZV infections may be documented by demonstration of a fourfold or greater increase in VZV antibody titer by using a sensitive test such as FAMA or ELISA. The presence of specific IgM in one serum specimen suggests recent VZV infection [39,40,318]. Persistence of VZV antibody beyond the age of 8 months is highly suggestive of intrauterine varicella, provided that there is no history of clinical varicella after birth [25]. Persistence of VZV antibody with no decrease in titer over several months in a young infant (as long as all sera are tested simultaneously) is highly suggestive of intrauterine infection. A FAMA or latex agglutination antibody titer of

1:4 or greater beyond 8 months of life is suggestive of immunity to varicella, provided that the patient has not received γ-globulin or other blood products in the previous 3 to 4 months. Physicians should be aware that no serologic test is 100% accurate for identifying individuals immune to varicella, although these antibody tests are generally reliable [319].

### Differential Diagnosis

Several diseases may be considered in the differential diagnosis of varicella in the newborn, including neonatal HSV, contact dermatitis, hand-foot-and-mouth syndrome and other enterovirus infections, and impetigo. In neonatal HSV, cutaneous lesions may be relatively sparse and may be absent altogether despite widespread visceral dissemination. Vesicles tend to occur in clusters, rather than in the more even distribution seen in chickenpox. Fever, marked toxicity, and encephalitis are more common in neonates with HSV. Stained smears of vesicle fluid (i.e., Tzanck preparation) are not helpful in differentiating HSV from varicella because both are characterized by multinucleated giant cells and intranuclear inclusion bodies. In cell cultures, HSV typically produces a widespread cytopathic effect in 24 to 48 hours, whereas the cytopathic effect caused by VZV is cell associated and focal and develops more slowly. Indirect immunofluorescence using monoclonal antibodies conjugated to fluorescein can be performed on smears of skin scrapings; if positive, the assay can identify VZV, HSV-1, and HSV-2 within several hours. Paired serum samples can be examined for increasing antibody titers to HSV and VZV antigens. It is exceedingly rare for varicella to develop in a newborn in the absence of any (i.e., infant or mother) exposure to varicella or zoster. In contrast, most infants with neonatal HSV have no recognized exposure to the virus.

Although 95% of cases of perinatal HSV are transmitted during delivery, a syndrome similar to congenital varicella syndrome, with limb and eye abnormalities, skin scarring, and zosteriform rashes, has rarely been observed after the unusual occurrence of intrauterine transmission of HSV [320,321]. In an infant with stigmata of congenital varicella syndrome whose mother has no history of varicella during pregnancy, congenital HSV should be considered. It may be impossible to make a definitive diagnosis immediately, unless the infant develops a vesicular rash from which the causative virus can be identified. Determination of antibody titers to HSV and VZV at presentation and when infants are 8 to 12 months old may be useful to establish a diagnosis.

In some cases of contact dermatitis, papules and vesicles may appear after exposure to specific chemical irritants. Typically, they appear on exposed body surfaces and do not have the characteristic distribution of chickenpox or smallpox.

In patients with hand-foot-and-mouth syndrome, a vesicular exanthem usually caused by coxsackievirus A16 or A5 may be observed during the enterovirus season (i.e., summer or early autumn). There are rarely more than a dozen vesicles, and they typically occur on the distal extremities, especially the palms and soles. Vesicular lesions that ulcerate quickly may also be seen in the oropharynx. The causative virus is readily isolated from vesicle fluid or from feces.

Impetigo may occur in neonates. In bullous impetigo (i.e., pemphigus neonatorum), large blebs are present instead of the smaller vesicles of chickenpox. This disease, which is caused by *Staphylococcus aureus*, may be associated with high fever, toxicity, septicemia, and death. Alternative diagnoses include syphilis, group B streptococcal infection, and incontinentia pigmenti, which may cause vesiculobullous lesions in a neonate.

Smallpox is traditionally part of the differential diagnosis of vesicular lesions in neonates. Although smallpox was eradicated, there is concern that the disease may reemerge because of bioterrorism. Classically, the vesicles of smallpox appear to be at the same stage of development instead of showing the pattern of crops over several days. A centrifugal distribution of the skin rash is prominent. The best approach in a suspicious situation is to rule out the possibility of VZV or HSV infection as described previously, preferably by immunofluorescence testing. If the test results are negative, a search for smallpox may be indicated, especially if the history of the patient warrants it. Accurate diagnosis may be achieved in hours by electron microscopy of the vesicle fluid or crusts; such microscopic examination reveals virus particles whose morphology is very different from that of viruses of the herpes family. Smallpox modified by exposure to vaccinia in the distant past and alastrim (i.e., variola minor) may be particularly difficult to distinguish from chickenpox. In suspicious cases, the CDC and local health department should be promptly involved.

Disseminated vaccinia is rare today because smallpox vaccine (i.e., vaccinia virus) is not routinely used, although a bioterrorism attack could change the scenario. Vaccinia can be considered in a neonate exposed postnatally to a person who has been recently vaccinated. The lesions resemble those of smallpox. Impression smears of vesicle fluid do not show intranuclear inclusions or giant cells. Laboratory diagnosis may be achieved by electron microscopy and immunofluorescence.

## Zoster

Zoster usually is easily recognized by the typical dermatomal distribution of the vesicular lesions. In the differential diagnosis, the main entity to be distinguished in the neonatal period is HSV appearing in a linear pattern. Identification of VZV or HSV DNA by PCR, antigen by immunofluorescence or virus isolation is the only reliable means of differentiating these entities when the distribution of the exanthem is linear. Contact dermatitis should also be considered in the differential diagnosis of zosteriform lesions in the neonatal period.

# THERAPY

## Treatment of the Mother

Acyclovir is the antiviral drug of choice for treatment of potentially severe or severe VZV infections [322,323]. Acyclovir itself has no antiviral action, but when it is phosphorylated by enzymes produced by cells infected

with VZV, it is incorporated as a DNA chain terminator, and it inhibits viral DNA polymerase. Because these actions occur only in virus-infected cells, acyclovir is well tolerated and associated with little toxicity. The drug is available in topical, oral, and intravenous formulations.

The safety of acyclovir has been shown in the past 35 years, and there is good reason to use this drug liberally in clinical situations for which it is indicated, even during pregnancy. Although most VZV infections in normal hosts are self-limited, there is a low but real fatality rate from varicella in adults. For this reason and because long-term toxicity of acyclovir in the fetus seems unlikely, acyclovir is recommended more often for use during pregnancy in women with varicella than previously. A registry of patients (and their offspring) who have received acyclovir during pregnancy has been established [189,190]. Generally, pregnant women who develop varicella should be treated with orally administered acyclovir and observed carefully. Pregnant women who develop severe varicella while receiving oral therapy, especially patients who develop pneumonia, should be promptly treated with intravenous acyclovir [324]. Supportive respiratory therapy (e.g., nasal oxygen, tracheostomy, ventilatory assistance) should be used as needed. Controlled studies of corticosteroids for varicella pneumonia are unavailable; steroids are not recommended. Antibiotics should be given if there is evidence of bacterial superinfection.

Anecdotal reports on the apparently successful use of acyclovir in pregnant women with varicella have been published, although controlled studies have not been performed. The data suggest that most women who develop varicella in pregnancy ultimately survive without sequelae [174]. This is undoubtedly the result of increasing awareness of the potential seriousness of the illness on the part of medical providers and the more liberal use of acyclovir today.

There is little information on the use of acyclovir for pregnant women with zoster. Presumably, because zoster would be expected to be self-limited in most women of childbearing age, there would be little need for antiviral therapy in this situation. Especially in the setting of an extensive rash or severe pain, use of acyclovir, particularly as oral therapy, should be strongly considered. Alternatively, one of the newer drugs, such as famciclovir or valacyclovir, can be used to treat pregnant women who develop severe zoster. The dose of famciclovir is 500 mg taken orally three times daily; the dose of valacyclovir is 1 g taken orally three times daily. Both medications are administered for 7 days. There is no information on the use of famciclovir or valacyclovir in pregnancy. Although famciclovir and valacyclovir are converted to acyclovir, and acyclovir is the active drug in the blood, there is more safety information on use of acyclovir in pregnancy, and for that reason it is probably preferable.

Acyclovir has been most effective when it is administered within 1 day after the onset of varicella and 3 days after onset of zoster. The usual adult dose for intravenous acyclovir is 10 mg/kg, given three times per day. Orally administered acyclovir has been found to have a modest effect on the fever and rash of varicella in otherwise healthy populations. A multicenter, double-blind, placebo-controlled, collaborative study involving 815 similarly treated children, who were given 20 mg/kg of acyclovir orally four times per day, shortened the course of illness by about 1 day [325]. The benefit to secondary household cases was not increased beyond that of primary cases. Similar results emerged from a study involving adolescents with varicella [326]. The modest benefit conferred by oral acyclovir therapy is not surprising in view of the self-limited nature of chickenpox in children and the poor oral absorption of acyclovir. There is a similar benefit for adults with varicella who were given oral acyclovir (800 mg taken five times each day for 5 days) within 24 hours of onset of rash [327,328].

In the double-blind, placebo-controlled study of Wallace and associates [328], involving 76 military recruits, the duration of illness was shortened by about 1 day, and the personnel were able to return to work 1 day sooner on average, if they received acyclovir. There is no information regarding treatment of pregnant women, and physicians are reluctant to extrapolate to them from studies involving mainly healthy young men. Given the possibility that acyclovir will help and is unlikely to harm, however, the drug should be strongly considered for most adults today with early varicella, pregnant or not.

### Treatment of the Newborn Infant

Although there is little information on the use of acyclovir in newborns for varicella, it has been used to treat many infants with neonatal HSV infection. In a study in which 95 infants received acyclovir (30 mg/kg/day given intravenously), no short-term or long-term toxicity was observed [323–325]. Pharmacokinetic studies have indicated that dose adjustments for acyclovir may be necessary in premature infants and infants with hepatic or renal dysfunction [329–331]. There are no data about the use of oral acyclovir for severe neonatal infections caused by VZV, and acyclovir is poorly absorbed when given by the gastrointestinal route. A dose of 1500 mg/m$^2$ of acyclovir, given intravenously in three divided daily doses, is recommended for infants with severe or rapidly progressing varicella. It is not recommended that infants with congenital varicella syndrome receive treatment with acyclovir except in the unusual setting of active zoster.

## PREVENTION

### Immunity to Varicella-Zoster Virus

Immunity to VZV may be incomplete in some persons. It was recognized years ago that waning of immunity to VZV might predispose a person to zoster [41]. That immunity to varicella might wane occasionally and result in a second case of chickenpox has been recognized only more recently. Immunologic evidence consistent with asymptomatic reinfection with VZV, manifested by an increase in VZV-specific IgG or IgA or the production of IgM and an increase in the cell-mediated immune response to VZV, has been documented in adults with a

household exposure to varicella [332,333]. Symptomatic reactivation with subsequent boosting of immunity is also possible, but is difficult to substantiate.

Clinical reinfection with VZV has been observed in some persons despite a positive antibody titer at exposure [334–337]. Most clinical reinfections are mild, however, which suggests that partial immunity to the virus may be present. Cellular immunity and antibodies may play a role in protection. In a study by Bogger-Goren and coworkers [338], children with positive cellular immune responses were likely to be protected against varicella after household exposure even if they were seronegative; in contrast, children with negative responses became infected. Secretory IgA against VZV has also been shown after chickenpox [339]. Although it has not been shown, it is hypothesized that cellular immunity at the mucosal level may play a role in protection against clinical varicella.

In addition to predisposing to reinfection with the virus, incomplete immunity to VZV is associated with development of zoster. In addition to clinical zoster, silent reactivation of latent VZV in persons who have had previous varicella probably occurs; this may be detected immunologically by an increase in antibody titer or the transient appearance of specific IgM, although it is difficult to rule out the possibility of an exogenous exposure [40,340–342]. Sometimes, clinical manifestations of zoster such as pain may occur in the absence of a rash—so-called zoster sine herpete. Silent reactivation of VZV in bone marrow transplant patients has been shown by PCR [343]. Zoster results in patients who have latent VZV infection when specific cell-mediated immunity is depressed [121,122,124,344]. Defective antibody responses to VZV glycoproteins have not been associated with development of zoster in immunocompromised persons [345]. Similarly, the increased incidence of zoster in elderly adults has been associated with loss of cell-mediated immunity to VZV [346,347], whereas antibody to VZV does not wane with age but tends to increase [348]. Immunity to VZV may be seen as a complex interaction between humoral and cell-mediated immunity responses, with the possibility of partial and complete immunity to the virus.

It is possible to provide humoral immunity to persons at high risk for developing severe varicella by passive immunization. Until more recently, this was done with VZIG. Although used successfully to prevent severe varicella, passive immunization has not prevented zoster in persons at high risk for it [349], and it is not believed to be useful to treat patients with varicella or zoster [350]. Passive immunization should not be employed to try to prevent development of varicella pneumonia in the pregnant woman with chickenpox or dissemination in an already infected infant. It is uncertain whether passive immunization of a woman with varicella can prevent infection of her fetus or development of congenital varicella syndrome. It is possible to increase cell-mediated immunity to VZV by immunization, and this approach was explored in several studies [351–353]. Results of a large, double-blind, controlled study in healthy vaccinees older than 60 years indicated that approximately half of more than 15,000 vaccinated individuals were protected from developing zoster [354]. This study by Oxman and colleagues also indicated that there are currently about 1 million annual cases of zoster in the United States.

## Passive Immunization against Varicella

Controlled studies have indicated that pooled immunoglobulin attenuates, but does not prevent, chickenpox when administered to susceptible family contacts [64] and that zoster immunoglobulin (ZIG) prevents clinical chickenpox when given to susceptible healthy children within 72 hours of household exposure [355]. Additional uncontrolled studies of immunocompromised children, such as children with leukemia receiving maintenance chemotherapy, at high risk for developing severe or fatal varicella have indicated that ZIG administered within 3 to 5 days of a household exposure usually modifies varicella so that the infection is mild or subclinical [356–358]. VZIG under the trade name VariZIG is manufactured in Canada and is available under an investigational new drug application expanded access protocol (telephone number for requests: 800 843-7477). The dose is 1.25 mL (1 vial or 125 U) for each 10 kg of body weight, with a maximum dosage of 6 mL (5 vials or 625 U) intramuscularly [197,359].

Passive immunization may prolong the incubation period of varicella [357]. Passive immunization has also been studied for its possible efficacy in modifying severe congenital varicella that may occur in the infant of a woman who develops chickenpox close to term. Infants born to women with the onset of varicella more than 5 days before delivery can be expected to have mild infection [62,133,289,360,361], and these infants do not require passive immunization. In contrast, infants born to women who develop varicella 5 days or less before delivery are at risk for developing disseminated or fatal varicella, and these infants can be expected to benefit from passive immunization. In an uncontrolled study by Hanngren and coworkers [290] of 41 neonates born to women who developed varicella between 4 days before and 2 days after delivery, the illness seemed to be modified. These infants received 1 mL of ZIG. Although the attack rate was 51%, and the incubation period averaged 11 days, there were no fatalities instead of the expected mortality rate of about 30%, and 13 (62%) of 21 had fewer than 20 vesicles with no fever. Two (10%) had severe infections, and one was treated with interferon.

In a similar study of VZIG by Preblud and colleagues [291], a similar varicella attack rate of 45% was observed in 132 infants. In this study, a dose of 125 U (1.25 mL) of VZIG was administered. The illness also seemed to be modified because of 53 infants with varicella, 74% had less than 50 vesicles, and only 10% had more than 100 vesicles. No antiviral therapy was given; there was one death in the group, but it was unclear that it was caused by varicella. The high attack rates of varicella in these studies compared with historical data have not been explained. In previous studies, infant attack rates of 24% in late [289] and overall [208] pregnancy have been reported. Successful passive immunization would, if anything, be expected to decrease the attack rate, rather than increase it. Nevertheless, the mildness of the illness and absence of mortality in these two studies are suggestive, if not proof positive, of successful passive immunization of infants born to women with

varicella at term. Since the introduction of ZIG and VZIG for use in appropriate neonates, fatalities from neonatal varicella have become rare.

It is recommended that VZIG or VariZIG be administered to infants whose mothers have the onset of varicella 5 days or less before delivery or in the first 48 hours after delivery [195,362,363]. A dose of 125 U (1.25 mL or one vial) should be administered intramuscularly as soon as possible after birth. Administration of VZIG to the mother before delivery of the infant is not recommended because a larger dose would be required to provide passive immunization to the infant, and no benefit to the mother would result. Early delivery of the infant of a mother with active varicella is also not recommended; the longer the infant remains in utero, the more likely there will be transplacental transfer of maternal antibody. A diagram of the relationship between maternal and infant varicella, development of maternal antibodies, and transplacental transfer of these antibodies is shown in Figure 22–5. Because women with zoster near term have high antibody titers to VZV, it is unnecessary to administer VZIG to their infants.

A few infants have developed severe or fatal congenital varicella despite prompt administration of VZIG in adequate dosage [364–369]. The reason for the severity of these cases is not fully understood, but they seem to be unusual or rare. Presumably, they were immunologically normal infants. Many of these children were reported from the United Kingdom, and the VZIG used there might have been less potent than that produced in the United States. The antibody titers of the two preparations were never compared. Passively immunized infants should be observed carefully, however, for the rare instance in which antiviral therapy may also be required. Rapid evolution of large numbers of vesicles, hemorrhagic manifestations, and respiratory involvement are indications for the use of intravenous acyclovir. Some investigators have recommended prophylactic use of intravenously administered acyclovir in any infant who develops varicella despite passive immunization [365,366,370,371], but this strategy has not been formally studied.

Based on the studies cited previously, most passively immunized infants who develop clinical illness have mild or moderate infections. Administration of intravenous acyclovir to all such infants who develop clinical illness would result in needless hospitalization of many infants and potential iatrogenic problems and would not be cost-effective. Unless additional data become available, intravenous acyclovir should be given only to infants who manifest early signs of potentially severe varicella. Infants who develop varicella despite passive immunization may be given a trial of orally administered acyclovir and observed carefully for the remote possibility of development of severe varicella, at which point intravenous acyclovir may be given.

Although it is recommended that VZIG or VariZIG be administered to infants born to women who develop varicella in the first 2 days after delivery, few reports indicate that this timing of birth at onset of maternal varicella is associated with increased risk to the infant. One of the reported infants with fatal varicella despite passive immunization was born to a woman who developed chickenpox on the 2nd postpartum day [367]. A child with severe varicella whose mother developed chickenpox 3 days after delivery has also been reported [372]. This child was treated with a leukocyte transfusion from her mother and thymic hormone and survived. In view of the absence of data indicating efficacy and the potential danger of graft-versus-host reaction after leukocyte transfusion in immunocompromised patients [373], this therapy cannot be recommended.

To minimize the possibility of infection of the infant, mother and infant should be separated until the mother's chickenpox vesicles have dried, even if the infant has been passively immunized. Normally, this would be 5 to 7 days after the onset of maternal rash. If the infant develops clinical varicella, the mother may care for the infant.

Pregnant women who are closely exposed to persons with varicella or zoster and who have no history of varicella and are seronegative may be passively immunized with VZIG [195]. Although precise information regarding dosage is unavailable, a dose of 5 mL (625 U) is usually recommended for adults. The rationale for passive immunization of the mother is to protect her from developing severe chickenpox.

Because some low birth weight infants may have low or absent levels of transplacentally acquired maternal VZV antibody, it is recommended that infants of less than 28 weeks' gestation or who weighed less than 1000 g at birth be passively immunized after close exposure

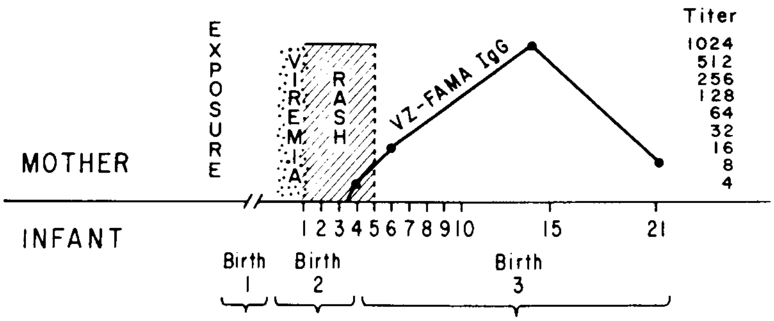

**FIGURE 22–5 Diagrammatic representation of transmission of varicella-zoster virus (VZV) and VZV antibody to a fetus in maternal varicella near term.** When the infant is born during the maternal incubation period (*1*), no varicella occurs unless the infant is exposed postnatally to the infection. When the infant is born 0 to 4 days after onset of maternal varicella (*2*), disseminated varicella may develop because the infection is not modified by maternal antibody. The onset of varicella occurs when the infant is 5 to 10 days old. Infants born 5 days or more after maternal varicella (*3*) receive maternal antibody, which leads to mild infection. This diagram is based on data for 50 newborn infants with varicella. *(Adapted from Gershon A. Varicella in mother and infant: problems old and new.* In *Krugman S, Gershon A [eds]. Infection of the Fetus and Newborn Infant. New York, Alan R Liss, 1975, pp 79–95.)*

[195,362,363]. There is no recognized age at which passive immunization is no longer recommended for these infants, but presumably it would be unnecessary in an infant more than several weeks old. Administration of passive immunization to term infants who are 2 to 7 days old at the time of exposure is not recommended, but it may be done optionally to decrease morbidity from varicella in this age group [374]. Passive immunization should not be used to try to control nosocomial varicella because it does not prevent varicella, but rather modifies it.

## Guidelines for Preventive Measures and Isolation Procedures in the Nursery

In contrast to transplacentally transmitted chickenpox, there is little evidence that postnatally acquired chickenpox (defined as disease beginning after the infant is 10 days old) is significantly more serious in infants than in older children (discussed in the preceding section). Nevertheless, despite the evidence cited previously indicating that nosocomial chickenpox among infants in the nursery is uncommon, it is desirable to institute preventive measures to minimize the possibility of transmission of infection to other neonates, mothers, and hospital personnel.

Any hospital patient isolated because of chickenpox or zoster should be in a separate room with the door closed, preferably in a room with air pressure negative compared with that in the corridor. Visitors and staff should be limited to persons immune to varicella. They should wear a new gown for each entry and wash their hands when leaving. Bedding and tissues soiled with respiratory excreta of the patient should be bagged and autoclaved. Special precautions for feces, urine, and needles or blood products are not required. Terminal disinfection of the room is likewise unnecessary.

Guidelines for isolation procedures and other measures are summarized in Table 22–9. In the vaccine era, these options rarely need to be considered because the incidence of varicella in children is rapidly decreasing. If there are siblings or others at home with active VZV infections at the time mother and infant are ready for discharge from the hospital, one of the following alternatives is recommended:

1. The mother and neonate may be sent home after boarding the older siblings with immune relatives until they are no longer infectious, generally when no new vesicles have appeared for 72 hours and all lesions have progressed to the stage of crusts.
2. The mother can return home while the neonate remains in the nursery.
3. The neonate can be boarded with a surrogate mother until the siblings are no longer infectious.
4. VZIG may be given to the newborn.

If siblings at home develop chickenpox at the time of delivery or shortly after birth, and the mother lacks a definite history of previous chickenpox, the first or last alternative is recommended. Serologic determination of the mother's immune status to varicella is recommended. Women with detectable VZV antibodies may be discharged home. Women who are seronegative should be offered varicella vaccine. Theoretically, if a woman has a history of varicella, her newborn should be at least partially protected from varicella. It seems prudent, however, to use a conservative approach, such as outlined here, because the real risk of varicella to the newborn is unknown.

When a mother with a negative history is exposed to chickenpox or zoster 6 to 20 days antepartum, she may become infectious before the onset of exanthem, during hospitalization for labor and the puerperium, assuming an average stay of 72 hours. This calculation is based on a minimum incubation period (exposure until onset of rash) of 10 days and a period of communicability preceding the exanthem by 3 days. When maternal exposure occurs less than 6 days before the onset of labor, the mother is unlikely to become infectious until after she has returned home. In either case, if the mother is exposed to chickenpox during the 20-day period antepartum, it is advisable to send the mother and infant home at the earliest possible date.

No special management is necessary for other mothers and infants in the nursery or for physicians and nurses potentially exposed in the delivery room or the nursery if they have previously had chickenpox. In the absence of a positive history, immediate serologic testing to determine the immune status of exposed hospital personnel may be performed when diagnostic facilities are available. Exposed personnel with negative histories may continue to work in the nursery for 8 days after exposure pending serologic results because they are not potentially infectious during this period. Personnel with positive VZV antibody titers in serum are probably immune. Nonimmune (seronegative) nursery and delivery personnel should be excluded from patient care activities between days 8 and 21 after exposure. Subsequently, they should be strongly encouraged to be immunized against varicella, and they may be given postexposure prophylaxis with varicella vaccine (discussed later).

The greatest risk of nosocomial chickenpox exists when a mother develops chickenpox lesions less than 5 days before delivery or in the immediate postpartum period. If the neonate is born with lesions (i.e., congenital chickenpox), the mother and her newborn should be isolated together and sent home as soon as they are clinically stable. Other exposed mothers and infants in the nursery may also be sent home at the earliest date possible. Restriction of patient care activities and serologic testing of exposed delivery and nursery personnel as described earlier should be instituted. Passive immunization of exposed infants is optional considering the usually benign course of postnatally acquired chickenpox.

When maternal chickenpox occurs within approximately 5 days of delivery or immediately postpartum and no lesions are present in the neonate, the mother and the infant should be isolated separately. Transplacentally acquired chickenpox, beginning 7 to 15 days after disease appears in the mother, ultimately develops in about one half of these neonates despite administration of passive immunization. The remainder are at risk for postnatally acquired chickenpox unless isolated from their mothers. If no lesions develop in the neonate by the time the mother is noninfectious, both may be sent home. Guidelines for exposed hospital personnel and patients are similar to those described previously.

**TABLE 22–9** Guidelines for Preventive Measures after Exposure to Chickenpox in the Nursery or Maternity Ward

| Type of Exposure or Disease | Chickenpox Lesions Present: Mother | Chickenpox Lesions Present: Neonate | Disposition |
|---|---|---|---|
| A. Siblings at home have active chickenpox when neonate and mother are ready for discharge from hospital | No | No | 1. *Mother*: If she has history of chickenpox, she may return home. Without a history, she should be tested for VZV antibody titer.* If test is positive, she may return home. If test is negative, VZIG† may be administered, and she may be discharged home. If she is antibody negative, 3 mo after VZIG she may also be immunized and sent home. A second vaccine dose should be given 4-8 weeks after the first<br>2. *Neonate*: Neonate may be discharged home with mother if mother has history of varicella or is VZV antibody positive. If mother is susceptible, administer VZIG or VariZIG to infant and discharge home or place in protective isolation |
| B. Mother with no history of chickenpox; exposed during period 6–20 days antepartum‡ | No | No | 1. *Exposed mother and infant*: Send home at earliest date unless siblings at home have communicable chickenpox.§ If so, may administer VZIG or VariZIG and/or vaccinate mother and discharge home, as above<br>2. *Other mothers and infants*: No special management is indicated<br>3. *Hospital personnel*: No precautions are indicated if there is history of previous chickenpox or zoster. In absence of history, immediate serologic testing is indicated to determine immune status.* Nonimmune personnel should be excluded from patient contact until 21 days after intimate exposure. Vaccination of nonimmune personnel should be encouraged. Immunized personnel who develop vaccine-associated rash should be excluded from work until rash has healed<br>4. If mother develops varicella 1–2 days postpartum, infant should be given VZIG or VariZIG |
| C. Onset of maternal chickenpox antepartum‡ or postpartum | Yes | No | 1. *Infected mother*: Isolate mother until no longer clinically infectious. If seriously ill, treat with acyclovir<br>2. *Infected mother's infant*: Administer VZIG† or VariZIG to neonates born to mothers with onset of chickenpox <5 days before delivery and isolate separately from mother. Send home with mother if no lesions develop by the time mother is noninfectious<br>3. *Other mothers and infants*: Send home at earliest date. VZIG or VariZIG may be given optionally to exposed neonates<br>4. *Hospital personnel*: Follow same recommendations as B-3 |
| D. Onset of maternal chickenpox antepartum§ | | | 1. *Mother*: Isolation is unnecessary if mother is no longer infectious<br>2. *Infant*: Isolate from other infants, but not from mother<br>3. *Other mothers and infants*: Follow same recommendations as C-3 (if exposed)<br>4. *Hospital personnel*: Follow same recommendations as B-3 |
| E. Congenital chickenpox | No | Yes | 1. *Infected infant and mother*: Follow same recommendations as D-1 and D-2<br>2. *Other mothers and infants*: Follow same recommendations as C-3<br>3. *Hospital personnel*: Follow same recommendations as B-3 |

**Send serum to virus diagnostic laboratory for determination of antibodies to VZV by a sensitive technique such as fluorescent antibody to membrane antigen, latex agglutination, or enzyme-linked immunosorbent assay. Personnel may continue to work for 8 days after exposure pending serologic results because they are not potentially infectious during this period. Antibodies to VZV >1:4 probably are indicative of immunity.*

*†VariZIG is available from Canada. Telephone number for requests is 800 843-7477. The dose for a newborn is 1.25 mL (1 vial). The dose for a pregnant woman is conventionally 6.25 mL (5 vials).*

*‡If exposure occurred <6 days antepartum, mother would not be potentially infectious until at least 72 hr postpartum.*

*§Considered noninfectious when no new vesicles have appeared for 72 hours, and all lesions have crusted.*

*VZIG, varicella-zoster immunoglobulin; VZV, varicella-zoster virus.*

In congenital chickenpox, lesions may be absent in the mother at the time of delivery, but present in the neonate. This may occur after rare subclinical infection in the mother [98] or because the onset of the exanthem in the infant occurs after the lesions in the mother have already healed. In either circumstance, the mother is not at risk and may be isolated with her newborn.

## Active Immunization against Chickenpox

A live-attenuated varicella vaccine was developed in Japan by Takahashi and colleagues [375]. This vaccine was licensed in 1995 by the U.S. Food and Drug Administration (FDA) for varicella-susceptible healthy children older than 1 year, adolescents, and adults. The vaccine is also licensed for routine use in many countries in Europe and in Asia, including Japan. The vaccine has proved to be safe and highly effective [47,376,377], and it is recommended for routine use by the American Academy of Pediatrics [362,378] and the CDC [195,363].

The vaccine protects against varicella in about 85% of individuals vaccinated and decreases the incidence of zoster in immunocompromised patients and presumably

in healthy vaccinees [122,359,376,377,379]. Since vaccine licensure, the incidence and complications of varicella have decreased by about 80% in the United States [359].

The major adverse effect of vaccination is development of a very mild transient rash about 1 month (ranging from a few days to 6 weeks) after immunization. Originally, there was concern that the vaccine virus could spread to others, but spread is extremely rare (1 instance per 10 million doses distributed). Contagion has not been reported in the absence of rash, and contact cases have uniformly been mild. There is no evidence of clinical reversion to wild-type VZV [46,157,359,376]. One instance of spread occurred when a healthy child was immunized and his pregnant mother developed mild varicella, from which the vaccine-type virus was identified by PCR [380]. The mother terminated the pregnancy; the products of conception were negative for VZV by PCR. There is no record of the Oka vaccine strain causing congenital varicella syndrome. It is important, nevertheless, to immunize susceptible women of childbearing age before they become pregnant.

The risk of immunizing healthy toddlers is calculated to be lower than not immunizing them and risking their development of natural varicella that would expose a varicella-susceptible pregnant mother to the fully virulent virus [381]. Widespread use of vaccine in the United States may decrease or even eliminate the problems of congenital malformations and severe varicella in the neonatal period, as has occurred with rubella. Although varicella vaccine–type virus has not been shown to cause congenital varicella syndrome, immunization during pregnancy is contraindicated. It is also recommended that immunized women refrain from becoming pregnant for at least 3 months after receipt of vaccine [195,362,363,378].

In 2006, it was recommended that all vaccinees receive two doses of vaccine at least 4 weeks apart [363]. The reported seroconversion rate after two doses of vaccine in healthy adults is about 90% [157,376]. Ideally, women should have serologic testing for immunity after immunization, but this is not recommended because negative antibody titer after immunization does not indicate vaccine failure, as commercially available ELISA antibody tests often fail to identify individuals who have responded to the vaccine [382]. The vaccine program in the United States has been highly successful; the vaccine is extremely safe. There is evidence of herd immunity with this vaccine [359].

The vaccine is under some scrutiny for one particular reason. The question has been raised whether widespread vaccination would lead to a significant increase in the incidence of zoster in unvaccinated persons. Zoster is less common in vaccinate persons than in persons who have had natural infection. After natural infection, reexposure to wild-type VZV can boost immunity to the virus, resulting in protection against zoster, presumably caused by control of reactivating virus before it results in illness [359]. The important question is how significant an increase in zoster is likely to be in the vaccine era. Based mainly on epidemiologic evidence and computer modeling, some studies predict a serious increase in zoster with accompanying fatalities [383,384]. The incidence of zoster is roughly 2 to 4 cases per 1000 person-years of observation [385]. If this incidence doubles as a result of routine vaccination, it is unlikely to represent an epidemic of zoster. Zoster is rarely fatal even in immunocompromised patients, in contrast to varicella, which continues to cause fatalities and has a higher mortality rate than zoster [386–389].

# MEASLES

Measles (i.e., rubeola) is a highly communicable childhood disease whose hallmarks are fever, coryza, conjunctivitis, cough, and a generalized maculopapular rash that usually appears 1 to 2 days after a specific enanthem (i.e., Koplik spots). The word *measles* means “little spots” and is derived from the Dutch word for the disease, *maeselen*, a diminutive of *maese*, meaning “spot” or “stain” [390]. Although measles was described in medieval times, it was not until the 17th century that Sydenham differentiated the disease from smallpox and scarlet fever.

## ORGANISM

### Classification and Morphology

Measles virus is a paramyxovirus, but some of its properties, such as the lack of neuraminidase, are distinct from properties of other members of this family. Similar to paramyxoviruses, measles virions have a diameter of 100 to 250 nm and consist of a helical ribonucleoprotein core surrounded by a lipid envelope.

In cell culture, virions replicate predominantly in the cytoplasm and are released from the cell surface by budding. The envelope of the virion is composed of at least two glycoproteins: F, which causes membrane fusion and is crucial for infectivity, and H, the hemagglutinin. A nonglycosylated matrix protein, M, also exists on the envelope. Antibodies to glycoprotein F inhibit viral infectivity [391]. Other internal structural proteins are the large protein (L), the phosphoprotein or polymerase (P), and the nucleocapsid protein (N). C and V proteins interact with cellular proteins and play roles in regulation of transcription and replication. The cellular receptors for measles virus are the complement regulatory protein CD46 expressed on human lymphocytes and many other human cell types and the signaling lymphocyte activation molecule (SLAM) CDw150 molecule [392–394].

Measles virus has been fully sequenced. Genomic data indicate that the viruses that caused the resurgence of measles in 1989–1992 were not new strains, that most of the reported cases in 1994–1995 were the result of international importation of virus, and that aggressive control measures in 1992 resulted in control of the viruses circulating at that time [395]. The latest data support this contention and indicate that there is no endemic measles in the United States; the few circulating viruses identified are imported from other countries [393,396].

### Propagation of Measles Virus

Primary cultures of human embryonic kidney and rhesus monkey kidney cells have proved to be superior to all others for the isolation of measles virus, although the agent has been adapted after several passages to numerous

continuous cell lines [392,394]. Cytopathic effect on primary isolation is not generally detected before 5 to 10 days. Rapid identification may be accomplished by use of immunofluorescent staining using monoclonal antibodies [392,394].

### Antigenic Properties and Serologic Tests

Measles virus isolates are antigenically homogeneous, although there are numerous genotypes. Some cross-reactivity of soluble ribonucleoprotein antigens and hemagglutinins has been observed among measles and the related viruses of rinderpest and canine distemper, but not with other paramyxoviruses. The hemagglutination inhibition test has essentially been replaced with more modern assays for antibodies [394].

ELISA presently is the most useful and sensitive method for measuring antibodies to measles virus [392,397]. A similar test that identifies specific IgM antibody and is useful diagnostically when only one serum specimen is available has also been developed [392,394,398,399].

## TRANSMISSION AND EPIDEMIOLOGY

### Transmission by Droplets and Fomites

Measles is the most communicable of the childhood exanthems [52,65]. The virus is spread chiefly by droplets expectorated by an infected subject in proximity to susceptible persons. Rarely, transmission may occur by means of articles soiled by respiratory secretions. There is some uncertainty concerning the precise portal of entry of the virus. Although the virus may gain access through the nose or the oropharynx, the work of Papp [400] suggests that the conjunctival mucosa is at least a possible portal of entry. Others have proposed viral entry at the tonsils [401].

Measles occurs worldwide in temperate, tropical, and arctic climates. Before the introduction of live measles vaccines, urban areas of the United States typically experienced epidemics at intervals of 2 to 3 years. In interepidemic years, few cases of measles occur, probably because the supply of susceptible persons has been exhausted. Additional births add to this pool, permitting epidemic transmission when the pool is sufficiently large. In the United States, the disease had a peak incidence between March and May. Seasonal variation is attributed to the crowding of children indoors and in schools in the winter, resulting in increased transmission. Amplification of each cycle leads to a progressively larger number of cases of measles by the end of the winter. Attack rates are highest among the lowest socioeconomic populations.

Patterns of disease vary strikingly with respect to age, incidence, and severity in different geographic regions. In urban areas of industrialized countries, measles infects predominantly children 2 to 6 years old, and the disease is relatively mild. In rural areas of the same countries, children are characteristically older when they contract the disease and may reach adulthood without becoming infected. For this reason, measles in pregnant women may be observed more often among women from rural or otherwise geographically isolated localities (see later discussion). A different pattern of disease is seen in less developed areas, such as equatorial Africa, where measles occurs predominantly in children younger than 2 years and has a high fatality rate [402]. Protein deficiency is associated with an increased incidence of complications, such as bronchopneumonia and death. Still another pattern of infection has been observed in extremely isolated regions of the world, where whole populations may never have experienced measles before its exogenous introduction. In a classic description of such an epidemic in the Faroe Islands in 1846, measles was observed to spread rapidly through an entire population, regardless of age, with an attack rate of virtually 100% [403]. Mortality rates tend to be higher in populations having little experience with measles. An extreme example is the Fiji Islands epidemic of 1875, in which 20,000 people, or about one fourth of the population, are said to have died [403].

The use of live-attenuated measles vaccine in the United States since 1963 has decreased the incidence of measles to less than 1% of its former incidence. Before 1963, there were about 400,000 reported cases of measles annually; a record low of 1497 cases was reported in 1983, but in the late 1980s and early 1990s, there was an increase in the incidence of measles that eventually came under control [371]. From 1989–1991, there were more than 55,000 reported cases with more than 120 measles-associated deaths reported to the CDC, but after 1991, the number of reported cases decreased significantly [404]. Measles occurring despite vaccination may be the result of primary vaccine failure, a “no take” for the vaccine, or secondary vaccine failure because of loss of immunity to measles after vaccination [405,406]. There is little evidence, however, that secondary immune failure (i.e., that protective immunity induced by measles wanes with time) is significant [405–408].

Since the requirement for two doses of measles vaccine in childhood was instituted in 1993, the number of annual cases of measles has declined to an all-time low. In 1995, 309 cases were reported, and in 1996, 508 cases were reported to the CDC [404]. Measles has become a rare disease in the United States; from 2000–2007, 63 annual cases were reported on average [409]. In the first 6 months of 2008, 131 cases of measles were reported to the CDC, however; 76% were ascribed to importations from Europe, Asia, and the Middle East. About 85% of cases were eligible for immunization [410]. The current vaccine coverage in the United States is greater than 90%, which is sufficient to prevent sustained transmission, although it does not prevent imported cases (http://www.cdc.gov/media/pressrel/2008/r080821.htm) [411].

### Incidence of Measles in Pregnant Women

Because measles is well controlled in the United States by immunization, it occurs less frequently during pregnancy than chickenpox.

## PATHOGENESIS

By analogy with other viral infections whose pathogenesis has been better delineated, the initial multiplication of measles virus is believed to occur in epithelial and lymphoid cells near the portal of entry. A transient viremia delivers virus to the reticuloendothelial system, where

further replication occurs. A second viremia, more severe and more sustained, disseminates virus to the skin, gut, respiratory tract, and other affected organs. In monkeys, this viremia may occur over 1 week before the appearance of the prodrome or exanthem. Measles virus replicates in and probably destroys lymphocytes in the peripheral blood [412], giving rise to a circulating lymphopenia. The symptoms of measles are probably attributable to inflammation accompanying necrosis of cells in which the virus is replicating. By the time the exanthem appears, 13 to 14 days after infection, measles virus is actively replicating in the skin, gut, and respiratory mucosa.

Electron microscopy of biopsy specimens of Koplik spots and cutaneous lesions reveals syncytial giant cells whose nuclear and cytoplasmic inclusions contain aggregates of microtubules that are 15 to 20 nm in diameter and characteristic of paramyxovirus infection [413]. This finding and the observation that convalescent measles serum injected into the skin can prevent the local development of the exanthem [414] suggest that replication of virus per se is directly responsible for the lesions. Nevertheless, it is possible that an interaction between viral antigen and antibody is required. The latter hypothesis is supported by the observation that immunosuppressed children who develop giant cell pneumonia caused by measles virus do not develop a rash and do not elaborate antibodies [396,415]. Virus titers in the viscera have already diminished considerably by the time the exanthem appears, and serum antibodies are readily detectable within 24 hours. There is also experimental evidence that T lymphocytes are important in the development of some symptoms of measles such as the rash and in recovery from the disease [416].

### Incubation Period for Measles Acquired by Droplet Infection

The usual interval between exposure to measles and onset of first symptoms (i.e., prodrome) is about 10 days; 12 to 14 days usually elapse before the onset of rash. Considerable variation may be observed, however [381]. The incubation period in modified measles (see "Clinical Manifestations") may last 17 to 21 days because of the presence of low levels of measles antibodies [417].

### Incubation Period for Hematogenously Acquired Measles

It has been claimed that infantile measles may be acquired by transfusion of maternal blood presumably containing measles virus [418]. Two infants developed typical enanthems and exanthems 13 and 14 days after transfusion, and their mothers developed measles exanthems 4 and 2 days after blood donation. The infants had not been visited by their mothers for 4 days and 1 day before transfusion. Hematogenous transmission may not have occurred, however, because the mothers may have been shedding virus from the respiratory tract at the time they last handled their infants.

Intrauterine hematogenous transmission is well documented (discussed later). In these cases, the onset of disease in the infant may occur almost simultaneously with that in the mother or after a variable interval that is less than the minimum time required for extrauterine infection by the respiratory route.

### Period of Communicability

Measles is more communicable during the prodrome and catarrhal stage of infection than during the period of the exanthem. Dramatic corroboration of this observation was provided during an epidemic in Greenland in 1962 [419]. Deliberate exposure of 400 susceptible persons to disease was achieved by having a patient on the first day of appearance of the exanthem cough twice in the face of each. Not a single transmission resulted. When the experiment was repeated with a patient during the pre-exanthematous period, measles was readily transmitted.

Patients with measles should be considered infectious from the onset of the prodrome (about 4 days before the appearance of the exanthem) until 3 days after the onset of the exanthem, although the risk of contagion abruptly diminishes 48 hours after the rash appears, concomitant with the appearance of circulating neutralizing antibodies. Measles virus is most readily recovered from respiratory secretions from 2 days before until 1 or 2 days after the onset of the rash.

## PATHOLOGY

The replication of measles virus in epithelial cells of the mucous membranes and skin leads to the formation of intranuclear inclusions and syncytial giant cells, which can contain 100 nuclei per cell (i.e., Warthin-Finkeldey cells) [420]. Focal hyaline necrosis of epithelial cells is accompanied by a subepithelial exudate containing predominantly mononuclear leukocytes. The pathology of cutaneous lesions and Koplik spots is essentially similar [413]. It is likely that virus replicates simultaneously in the skin and mucous membranes, but Koplik spots are detected earlier than the exanthem, probably because the epithelium that forms the roof of the lesions is thinner and more translucent in the mucous membranes.

Similar lesions containing the characteristic multinucleated giant cells may be widespread throughout the respiratory and gastrointestinal tracts. The pharynx, tonsils, bronchial epithelium, appendix, colon, and lymph nodes have been involved. Viral bronchitis occurs in most cases of measles. Necrotic columnar epithelial cells and giant cells are sloughed into the lumen of the bronchi and bronchioles. When this damage is extensive, the regenerating epithelium frequently undergoes squamous metaplasia and is accompanied by bronchial and peribronchial inflammation. Extension of the process into the alveolar septa results in interstitial pneumonitis. Secondary bacterial infection commonly supervenes, leading to a bronchopneumonia with purulent exudate.

Using immunofluorescence and immunoperoxidase methodology, measles virus has been shown in the placental syncytial trophoblastic cells and decidua in a 25-week fetus of a woman who developed gestational measles. The fetus was spared. It is postulated that placental damage induced by the virus, leading to hypoxia, is responsible for fetal death during maternal measles [421].

The pathologic signs of measles encephalitis are not readily distinguishable from signs of other postinfectious encephalitides, such as those caused by vaccinia, chickenpox, and rubella. The characteristic lesion is perivenous demyelination, often accompanied by mild perivascular infiltrates of mononuclear leukocytes, petechial hemorrhages, and microglial proliferation. Neuronal damage and meningeal inflammation are not prominent. Nuclear or cytoplasmic inclusions and giant cells are inconstant. Measles virus has been isolated infrequently from the brain or spinal cord, and it is unclear whether the pathologic changes in the brain are a direct result of measles virus or an allergic response to a virus-induced product or antigen-antibody complexes [422,423].

Because of the spectrum of pathology, including acute demyelinating encephalitis and acute hemorrhagic leukoencephalitis, it has been postulated that measles encephalitis is an autoimmune process. Myelin basic protein has been shown in the cerebrospinal fluid of patients with measles encephalitis, and the pathologic process has been likened to experimental allergic encephalitis as produced in animal models [424]. One theory regarding pathogenesis is that measles virus has an epitope similar to the epitope of the encephalitogenic sequence in central nervous system myelin (i.e., an instance of molecular mimicry leading to disease) [425]. A second form of encephalitis is caused by continued replication of measles virus in the brains of immunocompromised patients [426].

# CLINICAL MANIFESTATIONS

## Prodrome and Rash

The prodrome typically begins 10 to 11 days after exposure, with fever and malaise, followed within 24 hours by coryza, sneezing, conjunctivitis, and cough. During the next 2 to 3 days, this catarrhal phase is accentuated, with markedly infected conjunctivae and photophobia. Toward the end of the prodrome, Koplik spots appear. They are tiny (no larger than a pinhead), granular, slightly raised white lesions surrounded by a halo of erythema. Beginning with less than a dozen specks on the lateral buccal mucosa, Koplik spots may multiply during a 24-hour period to affect virtually all the mucous membranes of the cheeks and may extend to the lips and eyelids. Hundreds of spots may be present. At this stage, the lesions may be said to resemble grains of salt on a wet background. Koplik spots appear 1 to 2 days before the exanthem.

The rash, which appears 12 to 14 days after exposure, begins on the head and neck, especially behind the ears and on the forehead. At first, the lesions are red macules 1 to 2 mm in diameter, but over 2 or 3 days, they enlarge and coalesce. By the 2nd day, the exanthem has spread to the trunk and upper extremities. The lower extremities are involved by the 3rd day. The lesions are most prominent in regions where the exanthem appears first—the face and upper trunk. By the 3rd or 4th day, the exanthem begins to fade in the order of its appearance. A brown staining of the lesions often persists for 7 to 10 days and is followed by fine desquamation.

The clinical course of measles may be greatly altered by administration of immunoglobulin during the incubation period. In modified measles, the catarrhal phase may be completely suppressed, and the exanthem may be limited to a few macules on the trunk.

## Complications and Mortality

The most frequent complications of measles involve the respiratory tract. Otitis media and mild croup are common in young children during the catarrhal phase, but bacterial pneumonia is the complication that results in death most frequently. If carefully sought, fine rales and radiologic evidence of bronchopneumonia can be found during the early exanthematous phase in most patients. Cough may persist beyond the peak of the exanthem in uncomplicated measles, but when the fever fails to decline or recurs as the rash is fading, a bacterial superinfection is usually present. The chest radiograph may show consolidation. A peripheral blood polymorphonuclear leukocytosis is present. When bacterial superinfection occurs, antimicrobial therapy is indicated and should be directed against the most likely etiologic agents—*Streptococcus pneumoniae*, *S. aureus*, and *Streptococcus pyogenes*. Smears and cultures of sputum should be obtained, but in young infants it may be necessary to treat bacterial superinfection without a specific etiologic diagnosis because of the difficulty in obtaining adequate sputum and the potential gravity of the illness (see “Therapy”).

After otitis and pneumonia, encephalitis is the most frequent serious complication of measles. It is far less common than pneumonia. Encephalitis, including coma and gross cerebral dysfunction, is estimated to occur with a frequency of 1 per 1000 cases [422], but is probably more common if drowsiness, irritability, and transient electroencephalographic changes are accepted as evidence of encephalitis. This complication occurs in all age groups, including the neonatal period. A fatal outcome has been recorded in an infant, born in the hospital, who developed measles with encephalitis when 27 days old [423]. Measles encephalitis may occur at any stage of the illness, but appears most commonly 3 to 7 days after the onset of the exanthem. The initial symptoms are drowsiness and irritability, followed by lethargy, convulsions, and coma. The cerebrospinal fluid changes are those of a mild aseptic meningitis. Mental obtundation may clear over 1 to 4 days or may assume a more protracted course that is associated with a higher incidence of such sequelae as severe behavioral abnormalities and mental retardation. Death occurs in about 11% of cases [422].

Other complications of measles that have been described include thrombocytopenic purpura, appendicitis, myocarditis, subacute sclerosing panencephalitis, and reactivation or exacerbation of previously acquired tuberculosis. In a study of 3220 U.S. Air Force recruits with measles, whose mean age was 19 years, in 1976–1979, bacterial superinfection and elevated serum transaminase levels were observed in 30%, otitis was seen in 29%, sinusitis was seen in 25%, bronchospasm was seen in 17%, and pneumonia was seen in 3% [427].

The precise case-fatality ratio in measles is highly variable among different populations and at different periods in the history of the same population. From 1920–1950 in Massachusetts, deaths caused by measles declined

progressively during each successive 5-year period from 7.6 to 0.28 per 100,000 people, despite an approximately constant morbidity related to measles [403]. Because the decline preceded the widespread use of antibiotics, much of the change is attributed to improved social conditions: less crowding, improved nutrition, and medical care. In the United States since 1963, the case-fatality ratio has averaged about 0.1% based on reported cases, but it may be closer to 0.01% if estimated unreported cases of measles are included in the calculation [428]. The risk is considerably greater, however, in children younger than 1 year old.

The age-specific death rates for measles in the United States reported in 1949 (per 100,000 people) were 7.8 at younger than 1 year old, 2.8 at 1 to 4 years old, 1.3 at 5 to 9 years old, and 0.4 at 10 to 14 years old. Data obtained during an epidemic in Greenland in 1951 confirmed that death rates are higher for infants. The age-specific death rates (per 1000 people) were 26 for infants younger than 1 year and 15 for infants 1 to 2 years old; no deaths were recorded in children 2 to 14 years old [429]. In cases for which adequate information was available, all deaths of children younger than 1 year old apparently were caused by pneumonia, which occurred during the prodrome or shortly after the onset of the exanthem.

Children with underlying infection with HIV have been reported to be at risk for developing severe measles, and fatalities have been reported, especially in children who have developed AIDS [430]. In Africa, it has also been observed that infants born to HIV-infected women have lower titers of measles antibodies in cord sera than infants from women not infected with HIV. The outcome has been that these infants are at greater risk for developing measles early in infancy [431]. One adolescent with HIV infection who had previously received measles vaccine developed fatal measles pneumonia after the second dose [432]. Because the infection was proved to be from the vaccine virus, measles vaccine is no longer recommended for HIV-infected children who have developed AIDS or evidence of severe immunosuppression [404]. Immunocompromised children with underlying malignant diseases who have not been immunized are also at risk for developing severe and fatal measles [433–435].

## Maternal Effects of Measles

A pregnant woman with measles likely is at greater risk of serious complications and death than other adults with this disease. Some of the published experiences leading to this conclusion are summarized in the following paragraphs.

In the early part of the 20th century, fatality rates for pregnant women with measles were reported to be approximately 15%, mostly caused by pneumonia in the puerperium [436,437]. In the 1951 Greenland epidemic, 4 deaths (4.9%) occurred among 83 women who had measles during pregnancy or the puerperium. In contrast, 19 deaths (1.7%) occurred among 1099 nonpregnant women between the ages of 15 and 54 [429]. This difference is probably significant ($\chi^2 = 3.9$, $P = .05$). There was no significant difference in the frequency of pneumonia as a complication of measles among pregnant and nonpregnant women in the same age group, but heart failure was observed far more often in pregnant women with measles. Heart failure was observed in seven patients with gestational measles. Of these, three were in the second half of pregnancy, and four were in the puerperium. Although in some patients heart failure occurred during the prodrome, it occurred within 2 weeks after onset of the exanthem in most women.

Additional experience in the United States and Australia since 1940 supports the concept that measles during pregnancy is only rarely catastrophic. Among 24 women with gestational measles in an outbreak in rural Oklahoma, no deaths occurred, and serious morbidity was likewise not increased [438]. In another epidemic, reported in 1950 from Australia, 18 cases of gestational measles were observed. Complications were reported in only one case—a woman in the third trimester with measles pneumonia [439].

From 1988–1992 in the United States, when there was a resurgence of measles, numerous pregnant women developed this infection. Thirteen such women who were hospitalized in Houston, Texas, were reported because 7 (54%) had respiratory complications that were the basis for their hospitalization. They required supplemental oxygen and monitoring in the intensive care unit, and one woman died [440]. These women seemed to have primary measles pneumonia, rather than bacterial superinfection. Nine of these 13 women were treated with aerosolized ribavirin administered by facemask. Hepatitis, shown by elevations of transaminases, also occurred frequently in these women, but this is a common finding in nonpregnant adults that seems to be of little clinical importance. During this same period, medical records from 58 pregnant women from Los Angeles with measles were reviewed. Of these women, 35 (60%) were hospitalized for measles, 15 (26%) developed pneumonia, and 2 (3%) died [441]. Although it is difficult to prove that measles is more severe in pregnant than nonpregnant women, it seems likely to be so.

## Effects of Gestational Measles on the Fetus

### *Chromosomal Aberrations*

The possibility that measles occurring in pregnancy may damage the fetus is suggested by the observation that there is a high frequency of chromosomal breaks in leukocyte metaphase preparations between the 2nd and 5th day of the exanthem [442]. Other reports have not fully confirmed the preceding observations, however. Miller [443] found no chromosomal breaks in leukocytes of patients with measles who were examined 1 to 12 days after onset of the rash, but he attributed this discrepancy to methodologic differences involving more gentle treatment of the leukocytes. A report from Japan [444] also failed to show an increased frequency of chromosomal breaks per cell in patients with measles compared with those in normal subjects. A significant increase in chromosomal breaks was observed, however, in patients with Down syndrome who had measles, and it was inferred that their chromosomes were more sensitive to measles infection [444].

These chromosomal abnormalities are transient and disappear during convalescence. No studies have examined whether intrauterine exposure of the fetus to measles results in more lasting chromosomal aberrations.

### Abortion and Prematurity

The consensus of several reports dealing with the frequency of premature births is that this untoward event occurs more often in association with measles during pregnancy than in the pregnant population at large. In contrast to rubella, in which there is retarded intrauterine development, prematurity caused by measles is associated with normal intrauterine development, but premature expulsion of the fetus. Although there is no statistically valid proof that gestational measles also causes a higher rate of abortion, it seems probable that measles is responsible for some instances of abortion.

Among the retrospective studies is that of Dyer [438], who reported 24 cases of gestational measles from rural Oklahoma in 1938–1939. Uterine contractions, which typically occurred during the illness, were identified in 11 of the 24 women and caused premature delivery of the fetus in 9 (38%). In one woman in whom measles occurred at 18 weeks of gestation, the exanthem was followed by spontaneous abortion 7 days later. Two additional pregnancies were associated with premature births at 33 weeks of gestation. No abortions were associated with eight cases of measles occurring in the first trimester.

Adverse outcomes of gestational measles on the fetus involving 18 pregnant women with measles were reported in the epidemic in South Australia in 1950 [439]. There were three spontaneous abortions (17%), which occurred in one of seven women who had measles in the first trimester, one of eight women who had measles in the second trimester, and one of three women who had measles in the third trimester. Abortions followed the onset of the exanthem by 2 to 3 weeks in the patients who became ill in the first and second trimesters. The patient with measles in the third trimester had severe measles pneumonia and expelled a macerated fetus 7 weeks later. One live premature birth was recorded in the third trimester.

In the 1951 Greenland epidemic, birth or abortion occurred in 26 of the 76 pregnant women while they had measles [429]. Thirteen were term pregnancies. Of the remainder, spontaneous abortion at 3 to 5 months of gestation occurred in seven women (9%). There were six instances of premature delivery (8%), and perinatal death ensued in three. A retrospective analysis of 51 women in Greenland who developed measles during the first 3 months of pregnancy from 1951–1962 also suggested a high fetal death rate. One half with measles in the first 2 months and one fifth with measles in the 3rd month had spontaneous abortions [445]. Five infants born to women with measles during an outbreak in 1981–1982 in Israel were reported [446]. All were born prematurely (range 28 to 34 weeks) with a mean duration between maternal onset of illness and delivery of 3.5 days and a mean birth weight of 1496 g. None had any signs of measles at birth or in the neonatal period.

Controlled, prospective studies done in New York City during 1957–1964 showed a significant association between maternal measles and prematurity, but not between maternal measles and abortion. Low birth weight (<2500 g) was identified in 10 (16.7%) of 60 infants born to measles-infected mothers compared with 2 (3.3%) of 62 matched controls ($\chi^2 = 6.2$; $P < .025$) (see Table 22–4) [207]. When fetal mortality was examined in relation to gestational age (see Table 22–5), it was found that 3 deaths (15.8%) occurred in 19 cases of measles in the first trimester, 1 (3.4%) occurred in 29 in the second trimester, and 1 (5.9%) occurred in 17 in the third trimester [207]. These figures were not significantly different from those for fetal deaths in control pregnancies not involving measles. Of the five fetal deaths that occurred in pregnant women with measles, two of the deaths occurred within 2 weeks of maternal disease.

The resurgence of measles from 1989–1991 resulted in measles in numerous pregnant women. In the experience of Atmar and associates [440], there was an adverse fetal outcome in 4 (31%) of 13 pregnancies complicated by maternal measles. Two women gave birth in the 34th and 35th weeks, and one spontaneously aborted at 16 weeks during measles. One additional woman and her fetus died at 20 weeks. In a report from Los Angeles of 58 women, the incidence of abortion was 5 (9%), and the incidence of prematurity was 13 (22%) [441].

### Congenital Defects

The teratogenic potential of gestational measles for the fetus has been neither proved nor refuted because of the rarity of the infection during pregnancy, particularly during the first trimester when the process of organogenesis is most active. It seems clear, however, that if measles causes congenital malformations, it does so far less frequently than rubella. In contrast to gestational chickenpox, no particular constellation of abnormalities has been found among the sporadic instances of congenital defects that have occurred because of measles in the mother during pregnancy.

Isolated instances of buphthalmos [447], congenital heart disease [448], cleft lip [206], pyloric stenosis [448], genu valgum [447], cerebral leukodystrophy [445], and cyclopia [445] have been reported in infants born to mothers with measles diagnosed during the organogenic period. In these and other cases, documentation that the maternal illness was measles and not rubella or other exanthems is often lacking.

No congenital malformations were observed in four infants born to mothers who had measles during the first 4 months of pregnancy in the Oklahoma outbreak [438]. Similarly, in the 1951 Greenland epidemic, there were no congenital malformations among the infants of 76 mothers with gestational measles, although the number of cases that occurred in the first trimester is unclear [429]. After the epidemic in South Australia [439], two infants with congenital defects (one with Down syndrome and one with partial deafness) were recorded among infants whose mothers had measles during the first trimester. No birth defects occurred in infants born to eight mothers with measles in the second trimester and three mothers who had been ill in the third trimester. Although one of the five infants born during the outbreak in 1981–1982 in Israel was severely malformed, this was not caused by maternal measles, which had begun only a few days before birth. Five additional reported Israeli infants had no congenital anomalies, but all their mothers had measles just before delivery [446]. In the Houston report

of 13 pregnant women, the fetal gestational age at onset of maternal measles ranged from 16 to 35 weeks (mean 27 weeks). Follow-up of eight of these infants, delivered a mean of 12 weeks later (range 1 to 24 weeks), revealed that no infants had congenital malformations [440].

These analyses are incapable of establishing whether the incidence of congenital defects is increased as a result of gestational measles because they were uncontrolled. One controlled prospective study is inconclusive because only small numbers of pregnant women with measles could be studied. Among 60 children who were born to mothers who had gestational measles and were followed to the age of 5 years, only one congenital malformation was identified compared with a virtually identical incidence of one defect among 62 controls [173]. The defect in the infected group was bilateral deafness in an infant weighing 1990 g born to a mother who had measles at 6 weeks of gestation. If there is any increased risk of malformations from gestational measles, this risk seems to be small if it exists at all.

## Perinatal Measles

As in chickenpox, perinatal measles includes transplacental infection and disease acquired postnatally by the respiratory route. Because the usual incubation period from infection to the first appearance of the exanthem is 13 to 14 days, measles exanthems acquired in the first 10 days of life may be considered transplacental in origin, whereas disease appearing at 14 days or later is probably acquired outside the uterus.

### Postnatally Acquired Measles

Several reports describe cases of measles in which the onset of the exanthem occurred in infants 14 to 30 days old. The course of the disease in these cases was generally mild [438,449,450]. In one infant with notably mild illness and little fever, the illness began at 14 days of age. This neonate had been nursed by the mother, in whom the prodrome of measles developed on the 1st postpartum day. Because circulating and presumably also secretory antibodies appear within 48 hours of the onset of the exanthem, it is possible that the neonate's illness was modified by measles-specific IgA antibodies present in the mother's milk [438,449,450]. A report from Japan in 1997 described seven cases of measles in infants during the 1st month of life. No case was believed to be severe, although there were three infants with pneumonia, two of whom had received immunoglobulin at exposure [451].

Measles acquired postnatally may also cause more severe illness; when a mother developed the disease 20 days postpartum, her infant was quite sick with measles 10 days later, but complications such as pneumonia or otitis apparently did not develop [452]. There are reports of infants with prolonged presence of the measles genome in their mononuclear cells after vertical transmission of measles [453,454]. Rapidly progressive subacute sclerosing panencephalitis has also been reported after vertically acquired measles infection [455–460].

Outbreaks of nosocomial measles in the newborn nursery apparently have not been recorded in the 20th century. This is probably because of the low incidence of measles in the United States and other developed countries, nearly universal immunity in mothers in urban areas, and corresponding protection of the newborn by passive antibodies.

### Congenital Measles

Congenital measles includes cases in which the exanthem is present at birth and infections acquired in utero in which the rash appears during the first 10 days of life. In congenital measles, the incubation period, defined as the interval between onset of exanthem in the mother and in the infant, ranges from 2 [438] to 10 days [461] (mean 6 days). A nearly simultaneous onset in the mother and neonate implies that measles virus in the maternal bloodstream may sometimes cross the placenta in sufficient quantity to cause disease in the fetus without the need for many additional cycles of replication. The placenta may act as a barrier of limited effectiveness, however, as suggested by instances in which disease does not appear in the fetus until 10 days after its appearance in the mother. Even more cogent is the fact that maternal measles immediately preceding parturition by no means invariably involves the fetus. Of 44 pregnancies in which a maternal rash was present at delivery, exanthematous measles was reported in only 13 neonates (30%) [437].

Later reports include 13 instances in which maternal rashes with onsets ranging from 7 days antepartum to 3 days postpartum were associated with clinically apparent measles in the infant in only 3 cases (23%) [438,446,452,462]. Eight of these infants received immunoglobulin (0.25 mL/kg) at birth, however, including the three who developed measles [446,462]. During the Greenland epidemic of 1951, no examples of congenital measles were observed among infants born to 13 women who had measles at parturition [429]. It seems that most of these neonates do not experience subclinical measles without exanthem, but simply are not infected. This conclusion is supported by the observation that infants whose mothers had measles late in the third trimester are fully susceptible to infection later in childhood [437]. During the Faroe Islands epidemic of 1846, many pregnant women had measles, and 36 years later, their infants were infected as adults in a new epidemic in 1882 [452].

As in congenital chickenpox, the spectrum of illness in congenital measles varies from a mild illness, in which the rash is transient and Koplik spots may be absent, to rapidly fatal disease. The precise case-fatality ratio is uncertain because the course of measles in different populations has been so variable, even in older children and adults. Among 22 cases of congenital measles culled from the literature in which immunoglobulin prophylaxis was not given, there were seven deaths (Table 22–10) [437,438,452,461]. Approximately the same case-fatality ratio (30% to 33%) was observed whether the rash was present at birth or appeared subsequently. Although the number of observations is small, it seems that for premature infants with congenital measles, the death rate is higher (5 of 9) than for infants with congenital measles delivered at term (2 of 10). The death rate has also been high among premature infants born to women who had measles at parturition even when the infant never developed clinically apparent measles (see Table 22–10) [429,437].

**TABLE 22–10** Deaths in Neonates Whose Mothers Had Measles at Parturition

| Exanthem in Neonate | Neonatal Deaths* | Neonatal Cases | % |
|---|---|---|---|
| Present at birth | 4 | 12 | 33 |
| Appeared after birth | 3 | 10 | 30 |
| Did not appear | 7† | 16 | 44 |

*Stillborns excluded.
†All of these were premature infants reported in a single series [441].

**TABLE 22–11** Deaths from Congenital Measles in Relation to Date of Onset of Rash in Mothers

| Onset of Maternal Rash | Neonatal Deaths | Neonatal Cases | % |
|---|---|---|---|
| Antepartum | 4 | 15 | 27 |
| Postpartum | 3 | 11 | 27 |

Insufficient data are available to evaluate whether transplacentally acquired antibodies to measles virus may diminish the case-fatality ratio in congenital measles when the mother's exanthem appears more than 48 hours antepartum. The death rate from congenital measles does not seem to differ appreciably whether the maternal rash appears antepartum or postpartum (Table 22–11), but more precise information on the time of appearance of the maternal rash is needed to answer this question definitively. Although firm data are unavailable, administration of immunoglobulin at birth may also decrease mortality [440,446,462].

Most reports of death related to congenital measles do not specify the immediate cause, but pneumonia is among the leading complications.* Because nearly all reports of deaths preceded the antibiotic era, the current case-fatality ratio may be significantly lower than it was previously because of improved supportive care and appropriate antimicrobial therapy of bacterial superinfections.

## DIAGNOSIS AND DIFFERENTIAL DIAGNOSIS

The diagnosis of measles is easy when there is a history of recent exposure, and the typical catarrhal phase is followed by Koplik spots and a maculopapular exanthem in the characteristic distribution. Koplik spots are pathognomonic. The diagnosis is more difficult, however, during the prodrome (when the illness is maximally communicable) or when the illness and the exanthem are attenuated by passively acquired measles antibodies. Measles antibodies may be contained in transfused plasma or immunoglobulin, or they may cross the placenta to the neonate if the mother develops measles shortly before parturition. The atypical exanthem of measles in subjects who have been previously immunized with inactivated measles vaccine may potentially also cause diagnostic difficulties.

When the diagnosis cannot be made confidently on clinical and epidemiologic grounds, laboratory confirmation is indicated so that appropriate measures can be taken to prevent the occurrence of nosocomial measles among susceptible persons. Aids to rapid diagnosis include examination of exfoliated cells from the pharynx, nasal and buccal mucosa, conjunctiva, or urinary tract by direct staining for epithelial giant cells [464,465] or identification of measles antigens by direct immunofluorescence [466–468]. PCR assays can diagnose acute measles [392]. These tests are positive in more than 90% of patients during the prodrome and the period of the early exanthem. At later stages of the illness, the diagnosis may be confirmed by detecting measles-specific IgM antibodies in serum or increasing antibody titers in acute and convalescent sera [397,398,469]. Because serum antibodies appear within 48 hours of the exanthem, it is important that the acute-phase serum be collected at the onset of the rash or earlier.

The following diseases and conditions are to be considered in the differential diagnosis of measles. None is likely to occur in the newborn.

1. *Drug eruptions and other allergies*. Maculopapular exanthems may be caused by various drugs and chemicals in susceptible persons. A history of exposure is of paramount importance in distinguishing these causes from measles. An urticarial component may be seen in some instances of drug hypersensitivity, but is not present in measles.
2. *Kawasaki disease*. This illness is often confused with measles and vice versa in children younger than 5 years. Classic signs include conjunctivitis, red cracked lips, strawberry tongue, morbilliform or scarlatiniform rash, induration of the hands and feet, and usually a solitary enlarged cervical lymph node. In confusing cases, viral diagnostic procedures may be necessary to rule measles in or out.
3. *Rubella*. The maculopapular exanthem of rubella is finer and more transient. It undergoes a more rapid evolution and does not assume the blotchy configuration often seen in measles. The posterior cervical and postauricular lymphadenopathies of rubella are not present in measles, and conversely the prominent catarrhal symptoms in the prodrome of measles are not a feature of rubella.
4. *Scarlet fever*. The rash of scarlet fever is punctate and extremely fine rather than papular. It blanches on pressure and is accentuated in skin folds. The onset is typically abrupt without a prodrome. There is an accompanying sore throat, and the cheeks are flushed. Peripheral blood leukocytosis is usual, in contrast to the leukopenia of measles.
5. *Meningococcemia*. When the early rash of meningococcemia is maculopapular rather than petechial, it may be confused with measles. In contrast to measles, it has no characteristic distribution.
6. *Roseola*. The exanthem of roseola, which usually appears when the patient's temperature decreases to normal, typically appears on the trunk before it is evident on the head. It lasts only 1 or 2 days. Roseola, which is caused by human herpesvirus type 6, is seen most often in children younger than 3 years and is almost never seen in adults.

*References [437,438,440,446,462,463].

7. *Atypical measles*. This hypersensitivity disease is related to infection with measles virus in persons who received killed measles vaccine years ago. Killed measles vaccine was removed from the U.S. market in 1968. Extremely high measles hemagglutination inhibition antibody titers (e.g., 1:1 million) have been observed in patients with this disease.
8. *Other infections*. Rocky Mountain spotted fever, toxoplasmosis, enterovirus infections, parvovirus infection, and infectious mononucleosis may cause maculopapular exanthems resembling measles.

## THERAPY

The treatment of uncomplicated measles is symptomatic. Immunoglobulin has no proven value in established disease. Antibiotics are not indicated for prophylaxis of bacterial superinfections (i.e., otitis and pneumonia). When these complications develop, antimicrobial therapy should be selected on the basis of Gram stain and culture of appropriate body fluids, such as sputum. If culture specimens cannot be obtained or if the illness is grave, broad-spectrum antibiotics may be selected on the basis of the most likely offending pathogens. The antibiotic regimen for pneumonia, most commonly caused by *S. pneumoniae* or *S. aureus*, should include a penicillinase-resistant penicillin; the drug of choice for otitis media, which is usually caused by *S. pneumoniae* or *Haemophilus influenzae*, is amoxicillin. Vitamin A (200,000 IU orally once daily for 2 days for infants 12 months of age and older, 100,000 IU orally once daily for 2 days for infants 6 through 11 months of age, and 50,000 IU orally once daily for 2 days for infants less than 6 months of age) has been used to tread infants with measles and seems to decrease the severity of the infection [470–472]. The drug ribavirin has been used experimentally to treat severe measles in immunocompromised and other high-risk patients [473,474].

## PREVENTION

### Passive Immunization

Passive immunization is recommended for the prevention of measles in exposed, susceptible pregnant women, neonates, and their contacts in the delivery room or newborn nursery (see "Nosocomial Measles in the Nursery"). Therapy with intramuscularly administered immunoglobulin should be given as soon as possible after exposure. A dose of 0.25 mL/kg given within 72 hours of exposure to healthy children (0.5mL/kg for immunocompromised children; maximum 15 mL) is a reliable means of prevention of clinical measles, although immunoglobulin given later (7 days after exposure) or in smaller doses (0.04 mL/kg) may also prevent or at least modify the infection. It is recommended that passive prophylaxis be followed in 5 months or more by administration of live measles vaccine in patients old enough to receive it [362].

### Active Immunization

The currently recommended live measles vaccines are derivatives of the Edmonston B strain that have been further attenuated. They produce a noncommunicable infection, which is mild or inapparent. Fever occurs in about 5% of susceptible recipients. A mild rash is observed in 10% to 20% of susceptible recipients 5 to 10 days after administration. The vaccines induce seroconversion in 95% and prevent clinical disease in more than 90% of exposed susceptible recipients. Live-attenuated measles vaccines are contraindicated in pregnant women [362]. In one small series, Edmonston B measles vaccine and $\gamma$-globulin were administered to seven pregnant women, 18 to 34 years old, who were in the 2nd to 8th months of pregnancy. There were no serologic data. Three of the seven developed fever (>38.5° C) and rash. All were delivered of healthy infants at term [475]. Vaccination is likewise not usually recommended for infants younger than 12 months because the induction of immunity and the elaboration of antibodies may be suppressed by residual transplacentally acquired antibodies in the fetal circulation or other mechanisms. A single fatality in a young adult with HIV infection resulting from pneumonia after reimmunization has been reported [432].

In exposed populations having little experience with measles or in populations in which the incidence of natural measles before the age of 1 year is high, live vaccines may be given when infants are 6 to 9 months old, but should be followed by a second dose at 15 months to increase the seroconversion rate [362]. Data indicate that measles antibody titers are lower in women vaccinated as children than in women who have previously had natural measles and that the offspring of vaccinated women lose transplacentally acquired measles antibodies before they are 1 year old [476,477]. It is predicted that routine vaccination against measles may be recommended at 12 months rather than 15 months. Nevertheless, passive immunization should be given to protect young infants exposed during an epidemic.

Although the measles, mumps, and rubella (MMR) vaccine had an excellent safety record in 2000, the question was raised about whether this vaccine might result in autism in previously healthy children antepartum or postpartum [478]. The public in the United Kingdom became so fearful of this possibility that use of measles vaccine has decreased significantly, leading to reported outbreaks [479]. Potentially this development could lead to an increase in measles in pregnant women in the United Kingdom and other countries such as the United States where MMR coverage might decline.

### Nosocomial Measles in the Nursery: Guidelines for Prevention

Most women of childbearing age in urban areas are immune to measles because of previous natural infection or vaccination. Because it is amply documented that infants born to immune mothers are usually protected by transplacentally acquired antibodies, measles outbreaks in newborn nurseries are extraordinarily rare. Studies by Krugman and colleagues [480] indicated that before the introduction of live-attenuated measles vaccine, 94% of infants had passive hemagglutination inhibition antibodies when 1 month old, 47% had antibodies at 4 months, and 26% had antibodies at 6 months. The rarity of measles among mothers, newborns, and hospital staff in the newborn nursery makes it difficult to assess the precise

risk when the virus has been introduced. Nonetheless, the fact that age-specific mortality rates related to measles are highest in the first year of life (see previous discussion) justifies instituting measures designed to prevent disease in individuals exposed and the spread of infection to neonates of uncertain immune status (Table 22–12).

Infants born to mothers with an unequivocal history of previous natural measles or vaccination with live-attenuated measles virus are assumed not to be at risk when exposed to measles in the neonatal period. If siblings at home have measles in a communicable stage, neonates born to immune mothers may be discharged from the hospital with no treatment. In the absence of a maternal history of measles or measles vaccine, the mother's serum should be tested for the presence of antibodies to measles. If the mother's serum contains detectable levels of measles antibodies by a reliable method, the mother and neonate may be sent home. If specific antibodies are not detected in the mother's serum, the neonate and mother should not have contact with the older siblings until they are no longer infectious. The mother and neonate and any nonimmune older siblings without disease should receive immunoglobulin (0.25 mg/kg given intramuscularly) to prevent or modify subsequent measles infection that might have been incubating at the time of delivery.

If a mother without a history of previous measles or measles vaccination is exposed 6 to 15 days antepartum, she may be in the incubation period and capable of transmitting measles infection during the postpartum period before discharge from the hospital. In such a situation, it is optimal to test the mother for measles antibodies. If no antibodies are detected (or the test cannot be performed), and if she had been exposed less than 6 days antepartum, she could not transmit measles by the respiratory route until at least 72 hours postpartum. By this time in most instances, the mother would have been discharged from the hospital, and potential nosocomial transmission would not be a problem. In either event (exposure from 0 to 5 days or from 6 to 15 days antepartum), the exposed susceptible mother and her neonate

**TABLE 22–12** Guidelines for Preventive Measures after Exposure to Measles in the Nursery or Maternity Ward

| Type of Disease or Disease | Measles Present (Prodrome or Rash)* Mother | Measles Present (Prodrome or Rash)* Neonate | Disposition |
|---|---|---|---|
| A. Siblings at home with measles* when neonate and mother are ready for discharge from hospital | No | No | 1. *Neonate*: Protective isolation and IG are indicated unless mother had unequivocal history of previous measles or measles vaccination† <br> 2. *Mother*: With history of previous measles or measles vaccination, she may remain with neonate or return to older children. Without previous history, she may remain with neonate until older siblings are no longer infectious, or she may receive IG prophylactically and return to older children |
| B. Mother without history of measles or measles vaccination exposed during period 6–15 days antepartum‡ | No | No | 1. *Exposed mother and infant*: Administer IG to each and send home at earliest date unless there are siblings at home with communicable measles. Test mother for susceptibility if possible. If susceptible, administer live measles vaccine 5 mo after IG <br> 2. *Other mothers and infants*: Follow the same recommendations, unless clear history of previous measles or measles vaccination in mother <br> 3. *Hospital personnel*: Unless clear history of previous measles or measles vaccination, administer IG within 72 hr of exposure. Vaccinate $\geq$5 mo later |
| C. Onset of maternal measles antepartum or postpartum§ | Yes | Yes | 1. *Infected mother and infant*: Isolate mother and infant together until clinically stable, then send home <br> 2. *Other mothers and infants*: Follow same recommendations as B-3 except infants should be vaccinated at 15 mo old <br> 3. *Hospital personnel*: Follow same recommendations as B-3 |
| D. Onset of maternal measles antepartum or postpartum§ | Yes | No | 1. *Infected mother*: Isolate until no longer infectious§ <br> 2. *Infected mother's infant*: Isolate infant separately from mother. Administer IG immediately. Send infant home when mother is no longer infectious. Alternatively, observe in isolation for 18 days for modified measles,¶ especially if IG administration was delayed >4 days <br> 3. *Other mothers and infants*: Follow same recommendations as C-2 <br> 4. *Hospital personnel*: Follow same recommendations as B-3 |

**Catarrhal stage or <72 hr after onset of exanthem.*
*†Vaccination with live-attenuated measles virus (see text).*
*‡With exposure <6 days antepartum, mother would not be potentially infectious until at least 72 hr postpartum.*
*§Considered infectious from onset of prodrome until 72 hr after onset of exanthem.*
*¶Incubation period for modified measles may be prolonged beyond usual 10–14 days.*
*IG, immunoglobulin.*

should receive immunoglobulin and be sent home as soon as possible unless siblings at home have measles in a communicable stage.

If the mother's exposure occurred 6 to 15 days antepartum, prophylaxis with immunoglobulin should also be administered to the other mothers, neonates, and hospital personnel in the delivery room and nursery except those with a history of natural measles or vaccination with live-attenuated measles virus or who have detectable antibodies to measles virus. Globulin prophylaxis given within 72 hours of exposure prevents infection in nearly all instances, and in many cases it is effective for 7 days [403,481]. Immunoglobulin given after this period but before the prodrome usually results in modified measles infection with diminished morbidity [403,481]. Patients to whom immunoglobulin had to be given should later be vaccinated, after allowing an interval of at least 5 months so that residual measles antibody does not interfere with the immune response to the vaccine [403].

If a mother develops measles immediately antepartum or postpartum and her infant is born with congenital measles, the mother and infant should be isolated together until 72 hours after the appearance of the exanthem. Close observation of the neonate for signs of bronchopneumonia and other complications is warranted. Other susceptible mothers, neonates, and hospital personnel should receive immediate prophylaxis with immunoglobulin as outlined previously, followed by vaccination at a later date.

If a mother develops perinatal measles, but her infant is born without signs of infection, each should be isolated separately. The infant may be incubating transplacentally acquired measles or may be at risk for postnatally acquired droplet infection. In either case, the infant should receive immunoglobulin. The mother may be discharged with her infant after the 3rd day of exanthem. The neonate should be followed closely and observed for signs of modified measles, which may require 18 days of observation because of the abnormally long incubation period of modified measles [403].

The availability of virus diagnostic facilities varies, and the approach to potential nosocomial spread of measles may differ from place to place. If serologic testing is expensive or unavailable, it may be simpler to administer immunoglobulin to all exposed persons who do not have an unequivocal history of previous measles or previous vaccination with live-attenuated measles virus vaccine. Serologic testing of persons exposed who are thought possibly to be susceptible to measles, with administration of immunoglobulin to persons exposed who are truly susceptible, would seem to be the ideal management for prevention of nosocomial measles.

Neonates or mothers isolated because of measles require a separate room with the door closed and negative pressure ventilation. Only immune visitors and staff should enter the room. Gown and hand-washing precautions must be observed, and containment of bedding and tissues soiled with respiratory excreta by double bagging and autoclaving is indicated. Because measles virus is excreted in the urine during the early exanthematous phase, it is also advisable to treat the urine as potentially infectious and to disinfect bedpans. Terminal disinfection of the room is recommended.

# MUMPS

Mumps is an acute, generalized, communicable disease whose most distinctive feature is swelling of one or both parotid glands. Involvement of other salivary glands, the meninges, the pancreas, and the testes of postpubertal males is also common. The origin of the name is obscure, but probably is related to the Old English verb *to mump*, meaning "to sulk," or to the Scottish verb meaning "to speak indistinctly."

## ORGANISM

### Properties and Propagation

Mumps virus is a member of the paramyxovirus family and has most of the morphologic and physicochemical properties described for measles. Five antigens have been described: two envelope glycoproteins, a hemagglutinin-neuraminidase (H-N), a hemolysis cell fusion (F) glycoprotein antigen, and a matrix envelope protein. There are two internal antigens: a nucleocapsid protein (NP) and an RNA polymerase protein (P) [482].

Mumps virus is readily isolated after inoculation of appropriate clinical specimens into various host systems. Rapid identification may be accomplished by use of cells grown in shell vials and use of fluorescein-labeled monoclonal antibodies and molecular methods such as reverse transcriptase PCR [483–485]. The virus may be recovered during the first few days of illness from saliva, throat washings, and urine and from the cerebrospinal fluid of patients with mumps meningitis. Shedding of virus in the urine may persist longer, sometimes 2 weeks. Less commonly, the virus is present in blood, milk, and testicular tissue [482,484].

A highly sensitive ELISA useful for diagnosing and determining susceptibility to mumps has been described. This assay has also been used to diagnose acute mumps in one serum specimen by the presence of specific IgM [482]. The diagnosis may also be established by showing an increasing antibody titer in paired acute and convalescent sera.

## EPIDEMIOLOGY AND TRANSMISSION

### Period of Communicability

Mumps occurs worldwide and is endemic in most urban areas where routine vaccination is not practiced. In the United States, before widespread vaccination against mumps, the incidence was highest in the winter, reaching a peak in March and April. Mumps was principally a disease of childhood, with most infections occurring between the ages of 5 and 15 years. Mumps in infancy is very uncommon (discussed later). In the prevaccine era, approximately one third of infections were subclinical. Epidemics tended to occur in confined populations, such as those in boarding schools, the military, and other institutions. Since the introduction of live-attenuated mumps vaccine in 1967, the incidence of clinical mumps has declined dramatically in the United States, and mumps remains an extremely uncommon disease. In 2006, there was a resurgence of mumps, however, with 6584 cases reported to the CDC. Many occurred on college

campuses, and disease occurred in individuals who had received the recommended two doses of vaccine [486,487]. Mumps outbreaks are continuing to be problematic among young adults in the U.S. in 2010. Administration of a 3rd routine dose is being explored as a possible means of control.

### Incubation Period

The usual incubation period, measured between exposure to infection and onset of parotitis, is 14 to 18 days (range 7 to 23 days). Because the contact may be shedding virus before the onset of clinical disease or may have subclinical infection and be unrecognizable, the incubation period in individual cases is often uncertain.

### Incidence of Mumps in Pregnancy

The incidence of mumps in pregnancy is unknown. Because there is now little opportunity for exposure to mumps and many women are immune, the incidence is expected to be low. The incidence in prospective studies in the prevaccine era was variously estimated as between 0.8 and 10 cases per 10,000 pregnancies [71,173].

## PATHOGENESIS

Mumps is transmitted by droplet nuclei, saliva, and fomites. The precise pathogenesis of infection has not been established; although experimentally infected monkeys may develop parotitis, no animal model closely resembles human disease. After entry into the host, the virus initially replicates in the epithelium of the upper respiratory tract. A viremia ensues, after which there is localization in glandular or central nervous system tissues. Parotitis is believed to occur as a result of viremia, rather than the reverse, because in many instances generalized disease precedes involvement of the parotid gland, which may not be involved at all.

## PATHOLOGY

Studies of the pathology of mumps are few because the disease is rarely fatal. The histologic changes that have been observed in the parotid gland and the testis are similar. The inflammatory exudate consists of perivascular and interstitial infiltrates of mononuclear cells accompanied by prominent edema. There is necrosis of acinar and duct epithelial cells in the salivary glands and of the germinal epithelium of the seminiferous tubules.

There are few reports of placental pathology in gestational mumps. Garcia and associates [488] described a 29-year-old Brazilian woman with a history of two bleeding episodes during pregnancy who developed mumps in her 5th month. A hysterotomy was subsequently performed, yielding a macerated 90-g fetus. Necrotizing villitis and accumulation of necrotic material, mononuclear cells, and nuclear fragments were found in the intervillous spaces of the placenta. Necrotizing granulomas and cytoplasmic inclusions consistent with mumps virus infection were also identified. Two additional women with mumps in the 10th week and 2nd month of pregnancy underwent therapeutic abortions. Typical inclusion bodies were identified in both placentas and in the adrenal cortex of one fetus [488]. No serologic data were available on these three women, however, so it is possible that their parotitis was caused by an agent other than mumps virus.

## CLINICAL MANIFESTATIONS

The prodrome of mumps consists of fever, malaise, myalgia, and anorexia. Parotitis, when present, usually appears within the next 24 hours, but may be delayed for 1 week or more. Swelling of the gland is accompanied by tenderness to palpation and obliteration of the space between the earlobe and the angle of the mandible. The swelling progresses for 2 to 3 days, then gradually subsides, and disappears in 1 week or less. The orifice of Stensen duct is commonly red and swollen. In most cases, parotitis is bilateral, although the onset in each gland may be asynchronous by 1 or more days. The submaxillary glands are involved less often than the parotid and almost never by themselves. The sublingual glands are only rarely affected.

Orchitis is the most common manifestation other than parotitis in postpubertal males; it affects about 20% of this group of patients. Orchitis in infancy has been described, but is not well documented [489]. Oophoritis is far less common. It is associated with lower abdominal pain, and the ovaries rarely may be palpable. Oophoritis does not lead to sterility.

Aseptic meningitis may occur in children and adults of either sex, but is more common in males. Although pleocytosis of the cerebrospinal fluid may occur in 50% of cases of clinical mumps, signs of meningeal irritation occur in a smaller proportion of cases, variably estimated at 5% to 25%. The cerebrospinal fluid may contain 1000 cells/mm$^3$. Within the first 24 hours, polymorphonuclear leukocytes may predominate, but by the 2nd day, most cells are lymphocytes. In the absence of parotitis, the syndrome of aseptic meningitis in mumps is indistinguishable clinically from meningitis caused by enteroviruses and other viruses. The course is almost invariably self-limited. Rarely, cranial nerve palsies have led to permanent sequelae, of which deafness is the most common.

Mumps pancreatitis may cause abdominal pain. The incidence of this manifestation is unclear because reliable diagnostic criteria are difficult to obtain. An elevated serum amylase level may be present in parotitis or pancreatitis. The character of the abdominal pain is rarely sufficiently distinctive to permit unequivocal diagnosis. Other complications of mumps include mastitis, thyroiditis, myocarditis, nephritis, and arthritis.

The peripheral blood cell count in mumps is not characteristic. The white blood cell count may be elevated, normal, or depressed, and the differential count may reveal a mild lymphocytosis or a polymorphonuclear leukocytosis.

### Maternal Effects of Mumps

In contrast to varicella and measles, when mumps occurs in pregnant women, the illness is generally benign and is not appreciably more severe than it is in other women [489–498]. In a 1957 “virgin soil” epidemic of mumps among the Inuit, 20 infections occurred in pregnant women. Of these, only 8 (40%) were clinically apparent compared with an incidence of 57 clinically apparent cases (62%) among 92 nonpregnant women. Overt disease does not seem to be more common during pregnancy

[495]. Some complications, such as mastitis and perhaps thyroiditis, are more frequent in postpubertal women than in men, but probably do not occur more commonly in pregnant women than in other women [495]. Mumps virus has been isolated on the 3rd postpartum day from the milk of a woman who developed parotitis 2 days antepartum [499]. Her infant, who was not breast-fed, did not develop clinically apparent mumps. Aseptic meningitis, apparently without unduly high incidence or severity, has also been reported in pregnant women [500]. Deaths from mumps are exceedingly rare in pregnant women and in the population as a whole. One death has been reported in a woman who developed mumps complicated by glomerulonephritis at 8 months' gestation [500].

## Effects of Gestational Mumps on the Fetus

### Abortion

An excessive number of abortions is associated with gestational mumps when the disease occurs during the first trimester. In prospective studies of fetal mortality in virus diseases, Siegel and associates [207] observed 9 fetal deaths (27%) among 33 first-trimester pregnancies complicated by mumps compared with 131 (13%) of 1010 matched uninfected controls (see Table 22–5). This difference is significant ($\chi^2 = 5.6$; $P < .02$). Mumps-associated fetal deaths occurred in only 1 of 51 second-trimester pregnancies and none of 43 third-trimester pregnancies. In contrast to fetal deaths associated with measles, fetal deaths associated with mumps were closely related temporally to maternal infection: 6 of the 10 deaths occurred within 2 weeks after the onset of maternal mumps [207].

Many other reports describe isolated cases of abortion associated with gestational mumps. Most cases occurred in the first 4 months of pregnancy [490,495,496,498, 501–503]. In one instance, mumps virus was isolated from a 10-week fetus spontaneously aborted 4 days after the mother developed clinical mumps [503].

### Prematurity

In the only prospective study of low birth weight in relation to maternal mumps infection, no significant association was found [207]. Nine (7.7%) of 117 pregnant women with mumps gave birth to infants with birth weights of less than 2500 g compared with 4 (3.3%) of 122 uninfected pregnant women in a control group (see Table 22–4).

### Congenital Malformations

In experimentally infected animals, mumps virus may induce congenital malformations [504–506]. Definitive evidence of a teratogenic potential for mumps virus in humans has not been shown, however. Many reports describe the occurrence of congenital malformations after gestational mumps, but no data are available in most of these studies regarding the incidence of anomalies in uninfected matched control pregnancies. Swan [501] reviewed the literature in 1951 and found 18 anomalies in the offspring of 93 pregnancies complicated by mumps. These included four malformations originating in the first trimester (i.e., cutaneous nevus, imperforate anus, spina bifida, and Down syndrome) and nine originating in the second trimester (i.e., four cases of Down syndrome and miscellaneous other malformations). Other reports have described malformation of the external ear [491], intestinal atresia [498], chorioretinitis and optic atrophy in the absence of evidence of congenital toxoplasmosis [507], corneal cataracts [448], and urogenital abnormalities [508]. One case of hydrocephalus caused by obstruction of the foramen of Monro in an infant whose mother had serologically proven mumps during the 5th month of pregnancy has been described [509]. A similar phenomenon has been seen after extrauterine mumps with encephalitis [510] and in an animal model [506]. In the only controlled, prospective study, the rate of congenital malformations in children whose mothers had mumps during pregnancy (2 of 117) was essentially identical to the rate in infants born to uninfected mothers (2 of 123) [72]. The two affected infants, both of whom were mentally retarded, were not born to any of the 24 pregnant women who had mumps in the first trimester. Similarly, no association between gestational mumps and fetal malformations was reported by British investigators, who evaluated the outcomes of 501 pregnancies complicated by maternal mumps and found no significant differences compared with a control series [511].

### Endocardial Fibroelastosis

A postulated association between gestational mumps infection and endocardial fibroelastosis in the offspring was at one time the subject of much debate [512]. An extensive review of evidence for and against an etiologic role for mumps virus in this condition by Finland [513] in the 1970s was inconclusive, and there was little more information in the literature for the next 30 years. The issue remains unresolved. The rarity of mumps during pregnancy and the rarity of endocardial fibroelastosis as a possible sequela in the fetus make it unlikely that conclusive data will ever be obtained.

Molecular approaches seem to have shed new light on the issue. Using PCR, mumps virus genome was detected in two of two fatal cases of fibroelastosis [514]. In another study of 29 fatal cases of mumps, fragments of the mumps genome were identified in 20 cases [515]. Adenovirus was identified in the remainder. It was hypothesized that endocardial fibroelastosis is the end result of myocarditis. As mumps has become rare because of vaccination, endocardial fibroelastosis has also become rare [515]. The possible role of intrauterine mumps was not addressed in these two modern studies and may be impossible to evaluate further given the rarity of mumps in developed countries today.

## Perinatal Mumps

In contrast to congenital chickenpox and measles, congenital mumps or even postnatally acquired perinatal mumps has rarely been documented virologically or serologically. Although several cases of parotitis have been reported in women near delivery and their neonates and infants [495,516–519], the significance of these reports is often uncertain, especially when clinically apparent mumps only is present in the mother. Other viral, bacterial, and noninfectious causes are difficult to exclude

without laboratory evidence of mumps infection. Among the possible explanations for the rarity of transplacental and postnatally acquired mumps in neonates are the rarity of mumps today, protection of the neonate by passive maternal antibodies, exclusion of mumps virus from the fetus by a hypothetical placental barrier, relative insusceptibility of fetal and neonatal tissues to infection by mumps virus, and occurrence of infections that are predominantly subclinical.

Passage of mumps virus across the human placenta has occasionally been reported. Live-attenuated mumps virus has been recovered from the placenta of pregnant women (but not from fetal tissues) who were vaccinated 10 days before undergoing saline-induced abortion [520]. Mumps virus was isolated from two infants whose mothers had mumps at delivery. One infant had parotitis, and the other had pneumonia; presumably, transplacental transmission had occurred [518]. Mumps virus was also isolated from a fetus spontaneously aborted on the 4th day after the onset of maternal mumps [488]. Transplacental passage of virus should not be assumed to occur invariably, however, because in several instances passage could not be documented [488,521,522].

A differentiation between lack of susceptibility and subclinical infection as explanations for failure of the neonate to develop parotitis or other manifestations of mumps can be made only by adequate serologic investigations and viral isolation attempts. These data are unavailable. Several investigators have observed that clinically apparent mumps with parotitis [523,524] or orchitis [489] during the 1st year of life tends to be a very mild disease and that age-specific attack rates for manifest disease related to mumps increase progressively until age 5 years [525]. Antibodies to mumps virus are known to cross the placenta and to persist for several months [526].

# DIAGNOSIS AND DIFFERENTIAL DIAGNOSIS

The diagnosis of mumps is easy when there is acute, bilateral, painful parotitis with a history of recent exposure. More difficulty is encountered when the disease is unilateral or when the manifestations are confined to organs other than the parotid gland. In these cases, laboratory confirmation may be obtained by virus isolation or demonstration of an increasing antibody titer.

Among neonates, few conditions need be considered in the differential diagnosis. Clinical parotitis in this age group is rare. Suppurative parotitis of the newborn, usually caused by *S. aureus*, is most often unilateral [527]. Pus can be expressed from the parotid duct, and there is a polymorphonuclear leukocytosis of the peripheral blood. Other diagnostic considerations in neonates include infection with parainfluenza viruses and coxsackieviruses, drug-induced parotitis, and facial cellulitis. In addition to these conditions in neonates, the differential diagnosis in pregnant women includes anterior cervical lymphadenitis, idiopathic recurrent parotitis, salivary gland calculus with obstruction, sarcoidosis with uveoparotid fever, and salivary gland tumors.

Other entities should be considered when the manifestations appear in organs other than the parotid. Testicular torsion in infancy may produce a painful scrotal mass resembling mumps orchitis [489]. Aseptic meningitis related to mumps typically occurs in the winter and early spring, and enterovirus aseptic meningitis is most common in the summer and early autumn. Other viruses may also cause aseptic meningitis that is clinically indistinguishable from mumps.

# THERAPY

Treatment of parotitis is symptomatic. Analgesics and application of heat or cold to the parotid area may be helpful. Mumps immunoglobulin has no proven value in the prevention or treatment of mumps. Mastitis may be managed by the application of ice packs and breast binders. Testicular pain may be minimized by the local application of cold and gentle support for the scrotum. In some instances, severe cases of orchitis have seemed to respond to systemic administration of corticosteroids.

# PREVENTION

## Active Immunization

Live-attenuated mumps virus vaccine induces antibodies that protect against infection in more than 95% of recipients. The subcutaneously administered vaccine may be given to children older than 1 year, but its use in infants younger than this is not recommended because of possible interference by passive maternal antibodies. Usually, it is administered simultaneously with measles and rubella vaccines when children are 15 months old, with a second dose later in childhood. The vaccine is highly recommended for older children and adolescents who have not been immunized or had mumps; it is not recommended for pregnant women, for patients receiving corticosteroids, or for other immunocompromised hosts. Because of the resurgence of mumps beginning in 2006, in which vaccine failure after two doses was documented, needs for booster immunization are being explored, although no new policies have yet been implemented [486,487,528].

## Passive Immunization

Passive immunization for mumps is ineffective and unavailable.

## Prevention of Nosocomial Mumps in the Newborn Nursery

In contrast to chickenpox and measles, mumps does not seem to be a potentially serious hazard in the newborn nursery. No outbreaks of nosocomial mumps have been described in this setting, and transmission of mumps in a hospital setting is highly unusual [529]. Most mothers are immune, and neonates born to nonimmune mothers rarely develop clinically apparent mumps. Prudence dictates that mothers who develop parotitis or other manifestations of mumps in the period immediately antepartum or postpartum should be isolated from other mothers and neonates. The case is less strong for isolating a mother with mumps in the puerperium from her own newborn. In the hospital setting, isolation of patients with mumps from the time of onset of parotitis has proved to be ineffective in preventing the spread of disease [530]. Infected subjects shed mumps virus in respiratory

secretions for several days before the onset of parotitis or other manifestations recognizable as mumps.

At one time, exposed hospital personnel, particularly postpubertal males, and mothers with a negative history of mumps could be given mumps immunoglobulin, although the prophylactic effectiveness of this product was never established. This preparation is no longer available. Live-attenuated mumps virus vaccine has not been evaluated for protection after exposure, but may theoretically modify or prevent disease by inducing neutralizing antibodies before the onset of illness because of the long incubation period of mumps. It should be considered for exposed susceptible hospital personnel and puerperal mothers. Some hospitals have the facilities to test for susceptibility to mumps by measurement of antibody titers, whereas others do not. Testing for susceptibility could eliminate some use of vaccine for the previously described situation.

Isolation procedures for mumps include the use of a single room for a patient with the door closed at all times except to enter. Immune personnel caring for the patient should exercise gown and hand-washing precautions. Isolation is continued until parotid swelling has subsided. Terminal disinfection of the room is desirable. Updated CDC policy concerning persons with mumps recommends that patients with parotitis be isolated for 5 days after onset [531].

CHAPTER 23

# CYTOMEGALOVIRUS

**William Britt**

## CHAPTER OUTLINE

Human cytomegaloviruses (CMVs) constitute a group of agents in the herpesvirus family known for their ubiquitous distribution in humans and in numerous other mammals. In vivo and in vitro infections with CMV are highly species specific and result in a characteristic cytopathology of greatly enlarged (cytomegalic) cells containing intranuclear and cytoplasmic inclusions [1]. The strikingly large, inclusion-bearing cells with a typical owl's eye appearance were first reported by Ribbert [2] in 1881 from the kidneys of a stillborn infant with congenital syphilis. Subsequently, Jesionek and Kiolemenoglou [3] reported similar findings in another stillborn infant with congenital syphilis. In 1907, Lowenstein [4] described inclusions in 4 of 30 parotid glands obtained from children 2 months to 2 years of age. Subsequently, Goodpasture and Talbot [5] noted the similarity of these cells to the inclusion-bearing cells (giant cells) found in cutaneous lesions caused by varicella virus, and they postulated that cytomegaly was the result of a similar agent.

The observation of a similar cytopathic effect after infection with herpes simplex virus (HSV) led Lipschutz [6] and then others to suggest that these characteristic cellular changes were a specific reaction of the host to infection with a virus. The observation by Cole and Kuttner [7] that inclusion-bearing salivary glands from older guinea pigs were infectious for younger animals after being passed through a filter in a highly species-specific manner led to the denomination of these agents as salivary gland viruses. The cellular changes observed in tissue sections from patients with a fatal infection led to the use of the term *cytomegalic inclusion disease* (CID) years before the causative agent was identified.

In 1954, Smith [8] succeeded in propagating murine CMV in explant cultures of mouse embryonic fibroblasts. Use of similar techniques led to the independent isolation of human CMV shortly thereafter by Smith [8], Rowe and coworkers [9], and Weller and colleagues [10]. Smith [8] isolated the agent from two infants with CID. Rowe and coworkers [9] isolated three strains of CMV from adenoidal tissue of children undergoing adenoidectomy, including the commonly used laboratory-adapted strain of CMV, AD169. Weller and colleagues [10] isolated the

DOI: 10.1016/B978-1-4160-6400-8.00023-7

virus from the urine and liver of living infants with generalized CID. The term *cytomegalovirus* was proposed in 1960 by Weller and colleagues [11] to replace the names CID and salivary gland virus, which were misleading because the virus usually infected other organs and because the name *salivary gland virus* had been used to designate unrelated agents obtained from bats.

The propagation of CMV in vitro led to the rapid development of serologic methods. Using such antibody assays and viral isolation, several investigators quickly established that human CMV was a significant pathogen in humans. This ancient virus, similar to other members of the herpesvirus family, infects almost all humans at some time during their lives [12,13]. Evidence of infection has been found in all populations tested. The age at acquisition of infection differs in various geographic groups and socioeconomic settings, which results in major differences in prevalence among groups. The natural history of human CMV infection is complex. After a primary infection, viral excretion, occasionally from several sites, persists for weeks, months, or years. Episodes of recurrent infection with renewed viral shedding are common years after the primary infection. These episodes of recurrent infection are thought to be due to reactivation of latent viruses, increased levels of virus production from a source of persistent infection, or reinfections with a genetically different strain of CMV.

In immunocompetent hosts, CMV infections are generally subclinical. Infection can occur during pregnancy without consequences for the mother; however, it can have serious repercussions for the fetus. Although most immunocompromised hosts tolerate CMV infections without overt clinical symptoms, in some instances, such as in patients with acquired immunodeficiency syndrome (AIDS) and allograft recipients who have received immunosuppressive agents, CMV can cause disease of diverse severity, and the infection can be life-threatening. As a result of a long-standing and close host-parasite relationship, many—probably thousands—genetically different strains of CMV have evolved and circulate in the general population [14,15].

## VIRUS

CMV is the largest and structurally most complex member of the family of human herpesviruses. It has been classified as a beta-herpesvirus based on several biochemical criteria, such as the genome size, guanosine and cytosine content, slow replicative cycle, and restricted in vivo and in vitro tropism. Other members of this subfamily of herpesviruses include other mammalian CMVs and human herpesviruses 6 and 7, the agents associated with the exanthem roseola [16–18]. Early estimates of its size based on electron microscopic studies indicated that the CMV particle was approximately 200 nm in diameter, a finding consistent with measurements obtained by more contemporary techniques [19,20]. Intracellular and extracellular particles are heterogeneous in size, which is likely a reflection of the variability of envelope glycoprotein content.

The virus genome consists of more than 230 kilobase pairs of linear double-stranded DNA, making CMV nearly 50% larger than the alpha-herpesviruses with HSV and varicella-zoster virus [21]. In contrast to other beta-herpesviruses, including other CMVs, CMV contains terminal and internal repeated nucleotide sequences that enable the genome to exist in four isomeric forms, similar to HSV and other alpha-herpesviruses [22]. The biologic advantages that favor four isomeric forms of the genome of this virus have not been determined, but clearly depend on replication of the genome in a permissive cell [23].

The nucleotide sequence of several clinical isolates of CMV has been determined, and from analysis of these strains it is estimated that CMVs can encode more than 200 open reading frames (ORFs). Individual viral genes and ORFs are designated by their location in the unique long region (UL), unique short region (US), or internal or terminal repeat regions (IRS, IRL, TRS, TRL) of the prototypic genome of CMV [22,24]. In addition to the massive size of the genome, other post-transcriptional modifications can also increase the complexity of the coding sequence of CMV. A few CMV genes represent spliced transcripts, primarily those encoding immediate and early gene products. In some cases, multiple proteins can arise from a single gene by use of internal translation initiation sites.

Although in many cases experimental verification of viral specific proteins arising from predicted ORFs has not been accomplished, it is nevertheless obvious that the proteome of virus-encoded proteins within the virus-infected cell is exceedingly complex. Consistent with this postulate has been the complexity of the proteome of the virion revealed by mass spectrometry. This study indicated that the extracellular particle contained more than 100 unique virus-encoded proteins and an indeterminate number of host cell proteins [25]. Also, the organization of the CMV genome is similar to other herpesviruses in that conserved gene blocks encoding replicative and virion structural proteins can be found in similar locations [22,24]. The organization of the genome has allowed the assignment of positional homologues between members for different subfamilies of herpesviruses, an approach that has been instrumental in the identification of genomic coding sequences of CMV proteins. Outside of these conserved gene blocks are genes or gene families that are unique to individual betaherpesviruses. These genes are thought to impart specific in vivo tropism and the species-restricted growth characteristic of these viruses [22,26].

The CMV virion consists of three identifiable regions: the capsid containing the dsDNA viral genome, the tegument, and the envelope (Fig. 23–1A). The capsid of CMV consists of six proteins that have functional and structural homologues in other herpesviruses [27,28].

The capsid of CMV has been studied by high-resolution cryoelectron microscopy, and its structure is nearly identical to HSV except that it has slightly different internal dimensions secondary to the requirement that it must incorporate a genome that is about 60% larger than HSV. The capsid consists of 162 capsomere subunits consisting of 150 hexons and 12 pentons arranged in iscosahedral symmetry [19]. The subunits of the capsid are thought to be partially assembled in the cytoplasm of the infected cell followed by self-assembly using products of the viral

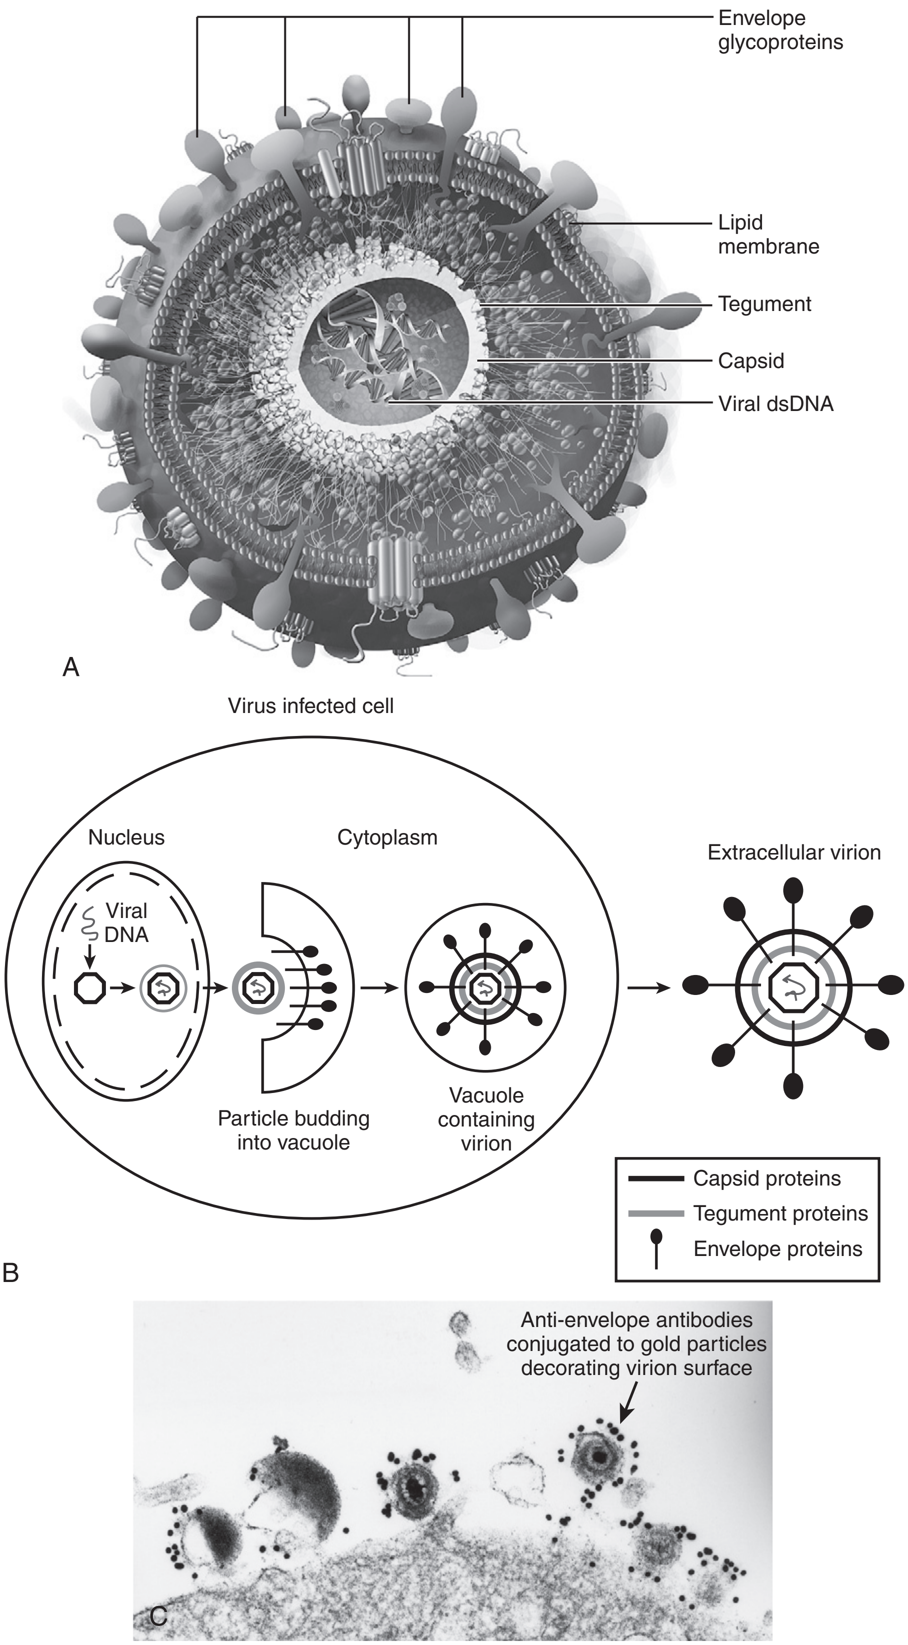

**FIGURE 23–1** **A,** Schematic representation of human cytomegalovirus virion. Viral double-stranded DNA (dsDNA) is shown encapsulated in protein capsid, which is surrounded by amorphous layer designated the tegument. Surrounding these structures is a lipid envelope into which glycoproteins are embedded. **B,** Proposed pathways of human cytomegalovirus assembly within infected cells. Note tegument particle budding into cytoplasmic vacuoles where it acquires its final envelope. Virus leaves cells by exocytic mechanism. **C,** Electron microscopic analysis of extracellular virus with envelope glycoprotein gN decorated with gold particles (*dark spheres*). *Schematic of virus (A) modified from original figure that was kindly provided by Jay Nelson, Daniel Streblow, and Andrew Townsend, Vaccine and Gene Therapy Institute, OHSU, Portland, OR.*

UL80a ORF [28]. Proteins encoded by this ORF serve as a scaffold for the assembly of the individual capsomeres [28]. When the shell is assembled, newly replicated concatemeric viral DNA enters the capsid shell through a portal generated by the portal protein and the action of virus-encoded protein complex termed the *terminase complex* generating the intranuclear capsid [27–31]. This replication strategy is very similar to that for generating double-stranded DNA bacteriophages.

Several steps in the assembly of the viral DNA–containing capsid are unique to CMV, including the cleavage of unit length DNA and the formation of the capsid portal. At least one of these steps in virus replication has been shown to be the target of antiviral drugs [31]. Capsids containing infectious DNA leave the nucleus by as yet poorly understood pathways and are enveloped in the cytoplasm. Evidence has been presented to suggest that CMVs could leave the nucleus by focal disruption of the nuclear membrane, whereas investigators have presented data suggesting that HSV can exit the nucleus through a similar mechanism or possibly through budding into the lumen of the endoplasmic reticulum [32–35]. A mechanism that is consistent with available evidence remains to be presented, although an operational pathway of virus assembly has been suggested by several lines of evidence (see Fig. 23–1B).

The tegument of CMV is the most structurally complex and heterogeneous structure in the virion. An undetermined number of viral proteins and, as was shown more recently, viral RNAs can be found in the tegument of infectious particles [36]. Although it is generally argued that the tegument has no identifiable structure and is usually described as an amorphous layer between the envelope and the capsid, more recent studies have argued that at least the innermost region of the tegument assumes the structure of the underlying icosahedral capsid [19].

Proteins within the tegument are characteristically phosphorylated and in many cases serve regulatory functions for virus replication. In addition, some tegument proteins seem to have a primary role in maintenance of the structural integrity of the virion. Tegument proteins have various functions in the infected cell ranging from blocking intrinsic cellular responses that degrade incoming DNA to directly stimulating cell cycle progression from $G_0$ to $G_1$ by degradation of the product of the retinoblastoma gene, *Rb*, and blocking progression at the $G_1$-S junction of the cell cycle [37–42]. In addition, other tegument proteins have been shown to enhance transcription from the IE genes and to accelerate the replication of viral DNA [43]. Other tegument proteins have been proposed to modify critical cellular responses to stress, such as through the mammalian target of rapamycin (mTOR) pathway, and to alter cellular structures, such as the infected cell nucleus, to facilitate nuclear egress of capsids containing viral DNA [44–49].

These examples illustrate the functional complexity of CMV tegument proteins and suggest that it would be difficult in some cases to assign a unique function to an individual protein in the replicative cycle of CMV. Finally, the tegument contains the most immunogenic proteins of the virions, including the immunodominant targets of T-lymphocyte responses and antibody responses [50–53]. In the case of one of the most abundant tegument proteins, pp65 (UL83 ORF), studies have shown that 2% to 5% of peripheral blood $CD8^+$ lymphocytes from CMV-infected hosts are specific for this single protein [52,54,55]. More recent studies have identified numerous CMV-encoded targets of $CD8^+$ and $CD4^+$ responses and have provided evidence that in some individuals 15% of total T-cell reactivity is directed at antigens encoded by CMV [52]. It is unclear why the normal host has devoted such a large percentage of peripheral $CD8^+$ lymphocyte reactivity to CMV, although persistence of the virus, which is facilitated by immune evasion functions, has been offered as an explanation.

The envelope of CMV rivals the tegument in terms of the number of unidentified proteins and the limited amount of information on the function of many envelope proteins. Sequence analysis of the CMV genome indicates that greater than 50 viral ORFs exhibit predicted amino acid motifs found in glycoproteins [14,21,56]. The number of glycoproteins that are present in the envelope of CMV is unknown, but at least 12 different glycoproteins have been defined experimentally [57–59].

More recent studies have suggested that the gM/gN complex represents the most abundant protein in the virion envelope, with gB and the gH/gL/gO complex being the second and third most abundant groups of glycoproteins in the envelope of laboratory strains of CMV [25]. The abundance of these different glycoproteins in the envelope of recent clinical isolates of CMV has not been studied, but the gH/gL/gO complex has been replaced with gH/gL/gUL128-131 complex in some of these viruses [60–62]. There seems to be a redundancy in function for several of these glycoproteins such that several are thought to be responsible for attachment and fusion; however, it also likely that these redundancies are a reflection of in vitro assays and that in vivo each of these proposed functions could be essential for virus infectivity, particularly in different cell types.

The envelope glycoproteins induce a readily detectable antibody response in the infected hosts, and neutralizing antibodies directed against gB, gH, gM/gN, and gH/gL/gUL128-131 complex can be shown in human CMV immune serum [63–68]. Considerable data from human and animal studies have indicated that antiviral antibodies directed at proteins of the envelope are a major component of the host protective response to this virus, such as illustrated by the decoration of the viral envelope with antibodies directed at specific glycoproteins (see Fig. 23–1C). These and other findings further show that envelope glycoproteins play a key role in the early steps of viral infection and represent a logical target for the development of prophylactic vaccines.

## CYTOMEGALOVIRUS REPLICATION

Virus replication begins when CMV attaches to the cell surface. Early studies suggested that the initial engagement of virion glycoproteins with cell surface proteoglycans was followed by more specific receptor interactions and fusion with the plasma membrane [69,70]. The cellular receptor for CMV was initially proposed to be epidermal growth factor receptor, and then later integrins

were proposed as receptors [71–73]. More recent findings have argued against the role of epidermal growth factor receptor as a receptor for CMV and have suggested that platelet-derived growth factor receptor can function at least as a signaling receptor for CMV [74,75].

Regardless of the specific receptor used by CMV, several studies have shown that CMV attachment and possibly fusion with the host cell membrane results in a cascade of cellular responses mediated by signaling pathways [70,76–79]. Signaling pathways can be activated by the attachment of ultraviolet (UV) light-inactivated, noninfectious virus and a single envelope glycoprotein indicating that the process of binding and fusion with the cell membrane is sufficient to induce these cellular responses. After infection with CMV, greater than 1400 cellular genes are either induced or repressed suggesting that infection with this virus elicits myriad host cell responses [78]. Included in these early responses are activation of transcription factors such as nuclear factor κB (NF-κB), increases in second messengers such as phosphoinositide-3 (PI3) kinase activity, increased expression of type I interferons and interferon-stimulated genes, and induction of responses that inhibit cellular innate responses that block virus infection (RNA-activated protein kinase [PKR]) or lead to apoptosis of the infected cell [80–84]. CMV infection prepares the host cell for virus replication and inhibits host cellular responses that could attenuate virus infection.

After attachment and penetration, the DNA-containing viral capsid is rapidly transported to the nucleus, likely using the microtubular network of the cell [85–87]. When in the nucleus, the immediate-early (IE) genes of the virus are expressed in the absence of any de novo viral protein synthesis, suggesting that either host or virion proteins are responsible for their induction. These genes include the abundant IE-1 and IE-2 genes. Both gene products arise from the same region of the genome and share some amino acid sequences secondary to RNA splicing the primary transcripts. The IE-1 gene product is a 72-kDa phosphoprotein (pp72, or IE-1) that is readily detectable throughout infection in permissive cells and is the target of antibody assays for detection of CMV-infected cells. The IE-2 gene product is a promiscuous transactivating protein and likely is responsible for activating many of the early and late genes of CMV and some cellular genes [24,88].

Additional IE genes include virus-encoded inhibitors of cellular apoptotic responses [89]. The remaining replication program of CMV is similar to that initially described for bacteriophages and for HSV and involves the coordinated and sequential temporal expression of viral genes and the coordinated inhibition of viral gene expression [24]. The regulation of CMV transcription, translation, and replication is exceedingly complex and beyond the scope of this chapter. It includes conventional modes of regulation including transactivation or silencing, or both, of promoter elements and splicing and regulation of spliced message transport from the nucleus; more recently, a role for virus-encoded micro-RNAs has been identified as a mechanism of viral gene regulation in infected cells [90–96]. A major goal of virus control of replication is to permit regulated expression of the viral genome.

The next set of viral genes expressed during infection are early or β genes. These genes are primarily composed of genes encoding viral proteins that are required for replication of viral DNA or alteration of cellular responses such as progression through the cell cycle or cellular apoptotic responses [24,97]. Examples of these genes are the viral DNA polymerase, alkaline exonuclease, ribonucleotide reductase, and other replicative enzymes. Some virion structural proteins are also made during this interval. The final set of viral genes that are expressed are the late or γ genes. These genes encode virion structural proteins and are required for the assembly of an infectious particle. The entire replicative cycle is estimated to take 36 to 48 hours in permissive human fibroblast cells. Abortive infections in nonpermissive cells have also been characterized, and viral gene expression generally is limited to the IE genes and possibly to a few early genes.

After viral DNA replication in the nucleus of infected cells, concatameric DNA is cleaved during packaging into the procapsid by mechanisms that closely resemble the pathway of bacteriophage assembly. More recent studies in the assembly of alphaherpesviruses have provided a much greater understanding of the mechanisms and pathways of viral capsid assembly and DNA packaging during herpesvirus replication. Interested readers are referred to these studies [98,99]. The viral capsid leaves the nucleus by as-yet-undetermined mechanisms and enters the cytoplasm as a partially tegumented, subviral particle. Assembly of the mature particle occurs in the cytoplasm of the infected cell in a specialized compartment that has been termed the *assembly compartment* [100]. It is believed that this is a modified cellular compartment of the distal secretory pathway [58,58–102]. Virion structural proteins are transported to this compartment, and presumably through a series of protein interactions, the virus is assembled and finally enveloped. This latter step is considerably complex because of the numerous virion glycoproteins that compose the envelope of infectious virion. Virus is presumably released by cell lysis in cells such as fibroblasts and by poorly defined exocytic pathways in certain other cell types.

Latency is a common theme of herpesviruses, particularly of the alphaherpesviruses such as HSV. The concept of latency with CMV in the human host and not at a single cell level is more controversial in that virus persistence in the host is more likely associated with chronic low-level productive infection and intermittent excretion. Latent CMV infection has been shown in macrophages obtained from infected nonimmunocompromised donors, however, and in in vitro models of infection with CMV [103–107]. The mechanisms that favor the establishment of latent infections are unknown, and the viral genome in latently infected cells is thought to be maintained as closed circular viral DNA that persists as an episome in latently infected cells and not by integration into the host DNA [108].

More definitive information is available on the signals that induce reactivation from latent infection. These signals include proinflammatory cytokines such as tumor necrosis factor-α and, possibly, interferon-γ [106,109]. It has been argued that in latently infected cells of the monocytic lineage, human CMV can become activated

and replicate CMV after exposure to these cytokines in vivo, such as in the setting of rejection of an allograft. This mechanism could explain aspects of the pathogenesis of CMV infection in uninfected allograft recipients transplanted with an organ from a CMV-infected donor [110–112]. It is also likely that such latently infected cells could account for the transmission of CMV from blood products from a seronegative host [113]. More recently, arguments for a role of host and viral micro-RNAs in maintenance of herpesvirus latency have been put forth, raising the possibility for even more complexity in the relationship between these large DNA viruses and their persistently infected host [90–96].

## CYTOMEGALOVIRUS CELLULAR TROPISM

CMV can be detected in a wide variety of cell types in vivo [114–116]. Studies using tissue from autopsies or biopsies have shown virus in almost every cell type, including epithelial cells, endothelial cells, smooth muscle cells, neuronal cells and supporting cells in the central nervous system (CNS), retinal epithelium, dermal fibroblasts, and cells of the monocyte/macrophage lineage. There seems to be a very limited restriction of the host cellular tropism in vivo. Routine virus isolation and propagation in vitro requires that the host cell be permissive for CMV replication. Although transformed cells are generally not susceptible to CMV infection, primary cells such as astrocytes, endothelial cells, smooth muscle cells, macrophages, and fibroblasts all have been shown to be permissive for CMV replication in vitro. The yield of infectious virus from these various cell types is highly variable, however, ranging from very low (macrophages) to high (fibroblasts).

Primary human fibroblasts are the most commonly employed cells for the recovery and propagation of CMV and if adequately maintained can yield $10^6$ to $10^7$ infectious particles/mL of supernatant from cultures infected with laboratory strains of CMV. In contrast, more recent clinical viral isolates often yield a fraction of this amount of virus, and almost all of the progeny virions are cell-associated. The explanation for the differences in replication phenotype is not completely understood, but more recent studies have suggested that it is the presence of a complex of glycoproteins in the envelope of recent clinical isolates, the gH/gL/gpUL128-131 complex, that not only allows extended cellular tropism of recent clinical isolates, but also results in increased cell fusion of primary fibroblasts and concomitant reduction in virus production [60]. Because the gH/gL/gpUL128-131 complex is not required for in vitro replication in fibroblasts and perhaps even inhibits replication, particularly the production of extracellular virus, viruses with mutations within genomic sequences encoding these proteins are selected against during prolonged in vitro culture. The expression of this glycoprotein complex by recent clinical isolates is required for their extended tropism, and these viruses infect primary endothelial cells, macrophages, and primary smooth muscle cells, whereas commonly used laboratory strains of CMV do not infect these cell types.

Although not understood, studies have provided some inkling as to possible mechanisms that lead to extended cellular tropisms of some recent clinical viral isolates. Assays of virus entry into cells have indicated that CMV can enter cells by direct fusion with the plasma membrane after engagement with a cell surface receptor by a pH-independent mechanism or, alternatively, after attachment to a receptor, internalization by endocytosis, and low pH fusion with the limiting membrane of the endocytic vesicle [117]. It has been shown that that the gH/gL/gpUL128-131 complex is required for the latter mechanism of entry, suggesting that cellular receptors on permissive cells other than human fibroblasts may dictate the cellular tropism of CMV.

# EPIDEMIOLOGY

## OVERVIEW

CMV is highly species specific, and humans are believed to be the only reservoir. CMV infection is endemic and without seasonal variation. Seroepidemiologic surveys have found CMV infection in every human population that has been tested [13]. The prevalence of antibody to CMV increases with age, but according to geographic and ethnic and socioeconomic backgrounds, the patterns of acquisition of infection vary widely among populations depending on the racial makeup of each population (Fig. 23–2) [118,119].

Seroprevalence based on testing of specimens from the Third National Health and Nutrition Examination Survey (NHANES III) ranged from 36% in individuals 6 to 11 years old to 88.8% in individuals 70 to 79 years old, showing the lifelong risk of acquiring CMV infection [118,119]. Overall in the United States, CMV seroprevalence was reported to be 58.9% [118,119]. Racial differences were apparent from this study with higher seroprevalence seen in African Americans and Hispanics than in whites [118,119]. A more recent study raised the possibility that the seroprevalence in urban African Americans in the United States may be decreasing such that an increasing number of individuals reach early adulthood without evidence of CMV infection [120]. This observation has not been confirmed in other populations, however. In addition to age and race, other risk factors for CMV infection included fewer years of formal education, government-sponsored insurance, and being born in another country [118,119].

Generally, the prevalence of CMV infection is higher in developing countries and among persons of lower socioeconomic status in developed nations. These differences are particularly striking during childhood. In sub-Saharan Africa, South America, and Asia, the rate of seropositivity was 95% to 100% among preschool children studied, whereas surveys in Great Britain and in certain populations in the United States have generally found that less than 20% of children of similar ages are seropositive.

The level of immunity among women of childbearing age, which is an important factor in determining the incidence and significance of congenital and perinatal CMV infections, also varies widely among different populations. Past reports indicated that seropositivity rates in young women in the United States and Western Europe range

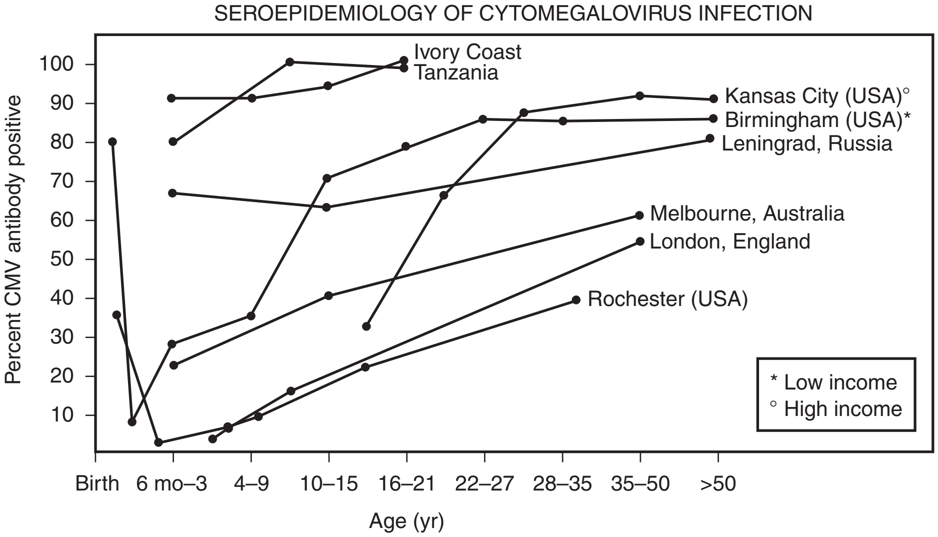

**FIGURE 23–2** Age-related prevalence of antibody to cytomegalovirus in various populations. *(From Alford CA, et al. Epidemiology of cytomegalovirus.* In *Nahmias AJ, Dowdle WR, Schinazi RE [eds]. The Human Herpesviruses. New York, Elsevier, 1981, p 161, with permission.)*

from less than 50% to 85%. In contrast, in sub-Saharan Africa, Central and South America, India, and the Far East, the rate of seropositivity is greater than 90% by the end of the 2nd decade of life. More importantly from the point of view of congenital infection, prospective studies of pregnant women in the United States indicate that the rate of CMV acquisition for women of childbearing age of middle to higher socioeconomic background is approximately 2% per year, whereas it is 6% per year among women of childbearing age of lower socioeconomic background, a finding that argues for the relationship between risks of exposure and rates of congenital CMV infection [121,122].

The modes of transmission from person to person are incompletely understood. The following features of CMV infection make it difficult to study the modes of acquisition. In most individuals, CMV infections are subclinical, including infections acquired in utero and during the perinatal period. Infected persons continue to expose other susceptible persons. Virus excretion persists for years after congenital, perinatal, and early postnatal infections. Prolonged viral shedding lasting more than 6 months in most individuals is also a feature of primary infection in older children and adults. Because recurrent infections are common, intermittent excretion of virus can be anticipated in a significant proportion of seropositive adults. Regardless of whether or not CMV is maintained as a latent infection with periodic reactivation or as a chronic persistent infection yielding low titers of infectivity, the virus continually spreads within a population.

A large reservoir of CMV exists in the population at all times. Transmission occurs by direct or indirect person-to-person contact. Sources of virus include urine, oropharyngeal secretions, cervical and vaginal secretions, semen, milk, tears, blood products, and organ allografts.

CMV is thought to have limited capacity to infect populations because the spread of infection seems to require close or intimate contact with infected secretions. Although at first glance this type of contact would seem to result in the limited exposure of most individuals to CMV, the unremitting nature of exposure to individuals persistently excreting virus could result in frequent infection, a finding consistent with seroprevalence to CMV exceeding 90% in most populations in the world. The prevalence of CMV infection is higher for populations of low socioeconomic status, possibly a reflection of factors that account for increased exposure to CMV such as crowding, sexual practices, and increased exposure to infants and toddlers. Sexual contact also contributes to the spread of CMV. Higher rates of seropositivity have been observed among men and women with multiple sex partners and histories of sexually transmitted diseases [123–127].

## BREAST-FEEDING

CMV is commonly excreted in milk collected postpartum from seropositive women [128–131]; the rates of excretion range from 13% to 32% by isolation of virus in tissue cultures to greater than 70% when tested by PCR. The peak of excretion is between 2 weeks and 2 months postpartum. The risk of transmission of CMV infection to infants ranges from 39% to 59%. The risk of transmission by lactating mothers correlates with viral loads of $7 \times 10^3$ genome equivalents/mL. CMV can be detected in different components of breast milk. There is consensus that milk whey is the material of choice to detect the virus during lactation. Fractions of milk containing milk cells are less likely to have detectable virus by either culture or PCR methods; this may explain why rates of viral isolation are lower in colostrum compared with mature milk. Most infants infected after ingestion of virus containing breast milk begin to excrete CMV between 3 weeks and 3 months of age.

Conservatively, it is estimated that nearly 40% of all infants nursed for at least 1 month by CMV-seropositive mothers become infected postnatally. Most of these infants chronically excrete CMV in urine and saliva, creating a large pool of infected infants. Because in most populations of the world the seroprevalence of CMV

infection in women of childbearing age is high (80% to 100%), and most women breast-feed their infants for more than 1 month, acquisition of CMV through ingestion of breast milk from a seropositive woman is quite high (Table 23–1).

## YOUNG CHILDREN AS A SOURCE OF CYTOMEGALOVIRUS

Certain child-rearing practices influence the spread of CMV among children. In 1971, Weller [1] suggested that the high rate of seropositivity among Swedish children was probably due to the frequent use of day care centers. Swedish children had a rate of infection that was three to four times higher than that observed in London or in Rochester, New York. As shown in Table 23–2, high rates of CMV infection among children attending day care centers were later confirmed in Sweden and have been reported in several studies in the United States [132–136].

The studies, which included a control group of children, confirmed that the rate of CMV infection was substantially higher among children in day care centers than in children who stayed at home [132–136]. In a study of 70 children of middle- to upperincome background in day care whose ages ranged from 3 to 65 months, the rate of CMV excretion in urine and saliva was 51% [132]. The lowest rate of excretion (9%) occurred in infants younger than 1 year, and the highest rate (88%) was among toddlers 2 years old. Twelve infants whose mothers were seronegative excreted CMV, which indicated that their infection was not congenitally or perinatally acquired. These findings have been corroborated by other investigators.

Similar results were reported by Adler [133], who also noted that greater than 50% of initially seronegative children acquired day care–associated strains of CMV as determined by restriction fragment polymorphism of viral DNA. The findings of Adler [133], which have been confirmed by others, showed that CMV is efficiently transmitted from child to child in the day care setting and that it was not unusual to find excretion rates of 20% to 40% in young toddlers [137]. In many instances, these rates of infection are substantially higher than the seroprevalence rates for the parents of the children and young adults in the cities where the studies were done [138]. Evidence strongly suggests that the high rate of CMV

infection among children in group day care is caused by horizontal transmission from child to child. The route of transmission that seems most likely is the transfer of virus through saliva on hands and toys [139,140]. CMV has been shown to retain infectivity for hours on plastic surfaces and has been isolated from randomly selected toys and surfaces in a day care center. No studies have shown CMV transmission through respiratory droplets.

These observations in day care centers indicate that transmission of CMV among young children is very efficient. When infected, these children excrete CMV in large quantities and for extended periods. With the changes in child-rearing practices now occurring in the United States and the resurgence of breast-feeding, significant changes in the epidemiology of CMV can be expected within the coming decades [138].

An important issue is whether children excreting CMV can become a source of infection for susceptible child-care personnel and parents, particularly women who may become pregnant. This type of transmission has been confirmed by genetic analysis of CMV DNA [141–144]. Seroepidemiologic studies suggest that parents often acquire CMV from their children who became infected outside the family. Yeager [145] first reported that 7 of 15 (47%) seronegative mothers of premature infants who acquired CMV in a nursery seroconverted within 1 year. Dworsky and colleagues [146] reported that the rate of seroconversion for women with at least one child living at home was 5.5%, significantly higher than the 2.3% rate for women from the same clinic who were pregnant for the first time or the rates for susceptible nursery nurses and for physicians in training. Taber and associates showed a significant association between seroconversion among children and seroconversion among susceptible parents and that in most cases the infection in a child preceded seroconversion in the parents [147].

There is also compelling evidence linking the acquisition of CMV by children in day care with subsequent infection in their mothers and caregivers [148–152]. Several studies have shown that CMV-seronegative parents have a significant risk of acquiring CMV infection if their infants and children attend day care. The highest risk of seroconversion is approximately 20% to 45% in parents with a child shedding CMV at 18 months of age. On average, parents acquired infection within 4.2 months (range 3 to 7 months) after their children became infected. Genetic analysis of viral DNA indicated that many of the strains isolated from the children, their parents, and their caretakers were related by epidemiologic characteristics. For caretakers working with young children in day care centers, the annual rate of seroconversion is approximately 10%, which is significantly higher than the 2% annual rate occurring in hospital employees matched for age, race, and marital status. These observations provided evidence that parents and women who work with children in day care centers have an occupational risk of acquiring CMV. It is reasonable to expect that 50% of susceptible children between the age of 1 and 3 years who attend day care will acquire CMV from their classmates and will become an important source of infection for susceptible parents and caregivers.

## MATERNAL INFECTION AND VERTICAL TRANSMISSION

Because maternal CMV infection is the origin of congenital infections and of most perinatal infections, it is important to review the relevant issues that pertain to vertical transmission. As used here, the term *vertical transmission* implies transmission from mother to infant.

### Congenital Infection

Congenital infection is assumed to be the result of transplacental transmission. In the United States, congenital CMV infection occurs in 0.2% to 2.2% (average 1%) of all newborns [121]. As shown in Table 23–3, the incidence of congenital infection is quite variable, however, among different populations.

The natural history of CMV during pregnancy is particularly complex and dependent on several characteristics of the population. Infections such as rubella and toxoplasmosis cannot serve as models, and in some aspects, the natural history of congenital CMV infections more closely resembles the natural history of congenital syphilis. In the case of rubella and toxoplasmosis, in utero transmission occurs only as a result of a primary infection acquired during pregnancy, whereas in utero transmission of CMV can occur as a consequence of primary and recurrent infections (reinfection or reactivation) [153,154].

Far from being a rare event, congenital infection resulting from recurrent CMV infection has been shown to be common, especially in highly immune populations. The initial clue was provided by three independent reports of congenital CMV infections that occurred in consecutive pregnancies [12,155]. In all three instances, the first infant was severely affected or died, and the second born in each case was subclinically infected. More convincing evidence came from a prospective study of women known to be seroimmune before conception [154]. As shown in Table 23–4, the rate of congenital CMV infection was 1.9% among 541 infants born to these seropositive women. The 10 congenitally infected infants were not infected as a result of primary maternal CMV infection because all mothers were known to have been infected with CMV 1 to several years before the onset of pregnancy.

Shortly after these studies were published, Schopfer and associates [153] found that in an Ivory Coast population in which virtually all inhabitants are infected in childhood, the prevalence of congenital CMV infection was 1.4%. More recent studies from Brazil and India have confirmed these early reports and shown again that the rate of congenital CMV infection is directly related to the CMV seroprevalence of the maternal population. In these populations, maternal seroprevalence is nearly 100%, yet the rate of congenital CMV infection was approximately 1% [156–158].

This phenomenon of intrauterine transmission in the presence of substantial maternal immunity has been attributed to reactivation of endogenous virus in some cases and to reinfection with different strains of CMV in other instances. Initially, support for a mechanism of reactivation as an explanation for recurrent infection came from the observation that the viruses isolated from each of three pairs of congenitally infected siblings were identical when examined by restriction endonuclease analysis [159]. In two of these three pairs, the first-born infant was severely affected, whereas the second-born sibling was subclinically infected, which suggested that virulence of infection was not related to strain and that maternal immunity in some way attenuated the fetal infection. Closer examination of these early data suggested, however, that in at least one of these cases, reinfection with a new strain of virus that differed genetically from the previous maternal isolate could explain the recurrent congenital infection.

More recent studies indicate that women who are CMV-seropositive can become reinfected with a different strain of CMV, leading to intrauterine transmission and symptomatic congenital infection [160]. This study assessed maternal humoral immunity to strain-specific epitopes of CMV glycoprotein H in serum specimens from women with preconceptional immunity who were sampled during a previous pregnancy and the current pregnancy. Of the 16 mothers with congenitally infected infants, 10 had acquired new antibody specificities against glycoprotein H compared with only 4 of the 30 mothers of uninfected infants. The women participating in this study were predominantly of low socioeconomic status; young; with a high seroprevalence of CMV; unmarried; and with a strong background of sexually transmitted diseases, including high rates of CMV excretion. The observations from this study have been confirmed in other populations, most recently in Brazil, in which reinfection occurred at an annualized rate of nearly 35% in a maternal population with near-universal seroimmunity to CMV (Yamamoto A, manuscript submitted for publication).

Intrauterine transmission of CMV in immune women explains the direct relationship between the incidence of congenital CMV infection and the rate of seropositivity as shown in Table 23–4. At present, it is extremely difficult to define by virologic or serologic markers which

patient may undergo a reactivation of CMV or reinfection with a new strain of virus, and it is nearly impossible to define the timing of intrauterine transmission with such reactivations or reinfections during pregnancy. The sites from which CMV reactivates to produce congenital infection are unknown and are likely inaccessible to sampling during pregnancy. Although CMV excretion is a common event during and after pregnancy, the simple isolation of virus during pregnancy is a poor indicator of the risk of intrauterine infection.

Virus can be shed at variable rates from single or multiple sites after primary or recurrent infections in women whether pregnant or not. Sites of excretion include the genital tract, cervix, urinary tract, pharynx, and breast. In pregnant women, virus is excreted most commonly from the cervix and, in decreasing order, the urinary tract and the oropharynx. In the immediate postpartum period, the frequency of viral shedding into breast milk is quite high and can reach 40% among seropositive women when assayed by conventional virus isolation and on the order of 70% to 90% when analyzed by PCR techniques. The rates of cervical and urinary tract shedding in nonpregnant women are comparable to rates found in pregnant cohorts with similar demographic and socioeconomic characteristics. Generally, rates of cervical shedding range from 5.2% for nonpregnant women enrolled in private obstetric practice or family planning clinics to 24.5% among women attending a sexually transmitted disease clinic [124,126]. Pregnancy per se has no discernible effect on the overall prevalence of viral shedding. The prevalence of excretion is lower (2.6%) in the first trimester, however, than near term (7.6%) [159]. This rate is comparable to the prevalence of genital excretion in nonpregnant women.

The rates of CMV excretion in the genital and urinary tracts of women are inversely related to age after puberty. In one study, the rate of genital CMV excretion decreased from 15% in girls 11 to 14 years of age to undetectable levels in women age 31 years and older [159]. From a peak of 8% in the younger group, urinary excretion fell to zero in women age 26 years and older. No CMV excretion occurred from either site in postmenopausal women.

A transient depression of cellular immune responses to CMV antigens during the second and third trimesters was reported in early studies, suggesting a role for altered immunity during pregnancy and CMV replication [161]. Other studies suggested that there was no generalized depression of cellular immunity based on the numbers of T lymphocytes, T-cell proliferative responses to other mitogens, and serum antibody titers. None of these mothers shed virus during the period of depressed cellular immune response, and they did not transmit the infection to their infants.

More recently, Lilleri and coworkers [162] identified a cohort of pregnant women with primary CMV infection and analyzed their virus specific T-cell responses. Several findings of this study are directly relevant to role of T lymphocytes in the natural history of congenital CMV. First, there was no difference in the kinetics of $CD4^+$ and $CD8^+$ CMV-specific responses between pregnant and nonpregnant women, a finding that argues against a virus-specific immunodeficiency during pregnancy that could increase CVM transmission to the fetus [162]. The duration of viremia was similar in women who transmitted virus to their fetuses and in women who failed to transmit virus, suggesting that obvious defects in control of virus replication cannot readily explain intrauterine transmission [162]. Women with primary infection who did not transmit virus to their offspring developed quantitatively higher CMV-specific $CD4^+$ T lymphocytes demonstrated responses, however, and developed these responses sooner than women who transmitted virus to their offspring [162]. This finding is provocative and suggested that the more rapid development of T-cell responses to CMV could in some way alter parameters of the maternal infection and lessen the risk of transmission to the fetus.

It has also been shown that antibody responses to glycoprotein B are significantly higher at the time of delivery in women with primary CMV infection who transmitted the infection in utero compared with women who did not, suggesting that the amount of antiviral antibody is not reflective of protection from transmission [163]. Analysis of the qualitative antibody response revealed lower neutralizing antibody titers in transmitters, however, suggesting an association between neutralizing activity and intrauterine transmission. In this study, a significant correlation was found between neutralizing titers and antibody avidity, indicating that antibody avidity maturation is crucial for production of high levels of neutralizing antibodies during primary CMV infection, a finding that at least on a superficial level parallels the findings of Lilleri and coworkers [162].

In a separate study, higher levels of transplacentally acquired maternal antibodies against glycoprotein B and neutralizing antibodies were observed in infants with symptomatic infection at birth who went on to develop sequelae [164]. These and other studies have limitations associated with measurement of immunologic functions in specimens from patients in which the timing of maternal infection, placental infection, or fetal transmission cannot be ascertained but only defined within large time intervals such as trimesters of pregnancy. Critical features of protective responses, such as the level of protective immune responses at the time of virus dissemination to the placenta and fetus, cannot be defined by such studies, and only correlations or associations can be inferred from existing data.

## Perinatal Infection

In contrast with the poor correlation that exists between CMV excretion during pregnancy and congenital infection, there is a good correlation between maternal shedding in the genital tract and milk and perinatal acquisition. As shown in Table 23–5, the two most efficient sources of transmission in the perinatal period were infected breast milk, which resulted in a 63% rate of perinatal infection, and the infected genital tract, particularly in late gestation, which was associated with transmission in 26% and 57% of the cases (natal infection). Viral shedding from the pharynx and urinary tract of the mother late in gestation and during the first months postpartum has not been associated with perinatal transmission.

**TABLE 23–5** Association between maternal excretion of CMV from various sites and subsequent infection of the infant

| Only Site of Maternal Excretion | No. Infants Infected/ No. Exposed (%) |
|---|---|
| Breast milk | |
| Breast-fed infant | 19/30 (63) |
| Bottle-fed infant | 0/9 (0) |

There is considerable variability in perinatal transmission of CMV throughout the world [165]. The age of the mother and her prior experience with CMV, which influence the frequency of viral excretion into the genital tract and breast milk, are important factors. Younger seropositive women who breast-feed have an increased risk for transmitting virus to their infants, especially women from lower socioeconomic groups [138]. In Japan, Guatemala, Finland, and India, where the rates of CMV excretion within the 1st year of life are extremely high (39% to 56%), the practice of breast-feeding is almost universal, and most women of childbearing age are seroimmune for CMV likely secondary to perinatal acquisition of CMV.

## SEXUAL TRANSMISSION

Numerous epidemiologic studies support the classification of CMV as a sexually transmitted infection, consistent with excretion of this virus in cervical secretions, vaginal fluid, and semen. In developing areas of the world, 90% to 100% of the population is infected during childhood, some by 5 years of age, providing an large reservoir for virus transmission. Sexual transmission in these populations could play a minor role as a source of primary CMV infection, but its importance in reinfection is suspected, although unproven. In developed countries, the infection is acquired at a lower rate in childhood, resulting in a burst in the prevalence of infection after puberty in some populations, an observation that parallels the acquisition of other herpesviruses such as Epstein-Barr virus. Several lines of evidence indicate that sexual transmission of CMV is at least partly responsible for this increase in seroprevalence.

As noted previously, an increased seroprevalence of CMV and excretion of virus has been found in women attending sexually transmitted disease clinics and in young homosexual men. Handsfield and colleagues [166] showed that previously infected individuals could be reinfected by a different strain of CMV. More recently, an association between CMV excretion and bacterial vaginosis has been described together with findings that argued that infection with multiple strains of CMV could be correlated with the presence of bacterial vaginosis, a sexually transmitted infection [127]. Evidence has also been provided for sexual transmission in general populations [167]. Among the many variables investigated, significant correlations were found among seropositivity to CMV, greater numbers of lifetime sexual partners, and past or present infection with other sexually transmitted infections.

## NOSOCOMIAL TRANSMISSION

Nosocomial CMV infection is an important hazard of blood transfusion and organ transplantation. In immunocompromised hosts, such as small premature newborns and bone marrow transplant recipients, transfusion-acquired CMV infection has been associated with serious morbidity and even fatal infection. The association between the acquisition of CMV infection and blood transfusion was first suggested in 1960 by Kreel and coworkers [168], who described a syndrome characterized by fever and leukocytosis occurring 3 to 8 weeks after open heart surgery. The reports that followed soon after expanded the syndrome to include fever, atypical lymphocytosis, splenomegaly, rash, and lymphadenopathy [169–172]. The term *postperfusion mononucleosis* was then proposed. Prospective studies incriminated blood transfusion as the major risk factor and showed that although the clinical syndrome occurred in approximately 3% of the patients undergoing transfusion, inapparent acquisition of CMV infection ranged from 9% to 58% as determined by seroconversion, a fourfold increase in complement-fixing antibody titers, or viral excretion occurring 3 to 12 weeks after surgery.

It has been estimated that the percentage of blood donors capable of transmitting CMV ranges from 2.5% to 12%. In a study of seronegative children receiving blood for cardiac surgery, the risk of acquiring CMV was calculated to be 2.7% per unit of blood [170]. A significant correlation between the risk of acquisition of CMV by patients labeled seronegative and the number of units of blood (total volume) transfused was noted early on [171]. Under conditions found in blood banks, CMV inoculated in whole blood persisted for 28 days, and CMV inoculated in freshly frozen plasma persisted for 97 days. More recent modifications of blood banking practices have greatly reduced the risk of CMV infection after blood transfusion; however, studies from Europe have shown that 15% of serologically negative blood donors as detected by commercial antibody assays may harbor CMV DNA in their peripheral blood and potentially transmit virus to a donor, a finding that may also explain that approximately 1% to 2% of recipients of blood transfusions from CMV-seronegative donors develop CMV infections [113].

The observation that two newborns who received large volumes of fresh blood subsequently developed symptomatic CMV infections led McCracken and associates [173]

to suggest an association between blood transfusion and clinically apparent postnatal CMV infection. Subsequent reports indicated an association between postnatal CMV infection and exchange transfusions [174]. Intrauterine transfusions have also been implicated in CMV infection of mothers and their infants and transmission from cord blood–derived stem cells.

CMV infections resulting from transfusion of blood products have also been shown to cause significant disease in newborn infants, particularly premature infants and infants born to women without immunity to CMV. Extremely premature infants born to seropositive mothers are also at increased risk because the transplacental transfer of specific antibodies does not occur until the later stages of gestation. Infected infants with passively acquired anti-CMV antibodies develop milder disease than infected infants without passively acquired antibodies [175]. This observation is a compelling argument for the role of antiviral antibodies in protecting the host against severe disease.

Transmission of CMV by transplantation of an allograft from donors previously infected with CMV represents a major clinical problem in allograft transplantation. Transplantation of a kidney from a seropositive donor into a seronegative recipient results in primary CMV infection in 80% of patients. The clinical manifestations of the infection vary widely, depending principally on immunosuppressive regimens. Most investigators have found that CMV infection has an adverse effect on the survival of the allograft. CMV was recognized as a major cause of morbidity and mortality in recipients of hematopoietic allografts and autografts and continues to represent an important opportunistic infection in these populations [176–179]. Interstitial pneumonitis is the most significant manifestation of the infection; mortality approached 100% before the availability of antiviral agents. CMV is excreted by 70% to 100% of recipients of heart transplants [180–183]. Severe disease has traditionally been thought to be associated more often with primary than with reactivated infection. Studies in several transplant populations have documented significant disease after superinfection with strains of CMV derived from the allograft [184–187]. These early findings and subsequent findings argue for a complex relationship between host immunity, infection with new strains of virus, and protective responses. The demonstration of CMV nucleic acid in kidneys of infected donors and of latent CMV in cells of macrophage/monocyte lineage showed that the transplanted organs and hematopoietic allografts can serve as the source of virus in transplant recipients [110].

Nosocomial transmission is possible in the nursery setting, which suggests that workers' hands or contaminated fomites might be involved. The very low rate of CMV infection in newborn infants of seronegative mothers who are not exposed to other important sources such as seropositive blood products indicates that transmission of CMV via fomites or workers' hands is uncommon.

## TRANSMISSION TO HOSPITAL WORKERS

Because hospital workers are often women of childbearing age, there has been concern about occupational risk through contact with patients shedding CMV. As illustrated in Table 23–6, most older studies indicated that

**TABLE 23–6** Rates of Primary CMV Infection Among Health Care Workers and Others

| Study | Group | Numbers | Seroconversion (%/yr) |

**Only study in a children's hospital reporting a statistically significant difference in relation to occupational contact.*

*Modified from Pass RF, Stagno S. Cytomegalovirus.* In *Donowitz LG (ed). Hospital Acquired Infection in the Pediatric Patient. Baltimore, Williams & Wilkins, 1988.*

the risk was not significantly different from the general population.

The risk for CMV seroconversion among hospital personnel is a function of the prevalence of CMV excretion among patients, the prevalence of susceptible health care workers, and the degree of their exposure to infected patients. Generally, among hospitalized infants and children, viruria occurs in approximately 1% of newborns and 5% to 10% of older infants and toddlers.

Working with hospitalized children inevitably leads to contact with a child shedding CMV; however, it is important that workers who develop a primary infection not assume that their occupational exposure or contact with a specific patient is the source of infection. Three old reports illustrate this point. Yow and coworkers [188], Wilfert and associates [189], and Adler and associates [149] described health care workers who acquired CMV while pregnant and after attending patients known to be excreting CMV. In each of these reports, the source of CMV for hospital workers was not from patients. With the implementation of universal precautions in the care of hospitalized patients, the risk of nosocomial transmission of CMV to health care workers is expected to be much lower than the risk of acquiring the infection in the community.

## PATHOGENESIS

The disease manifestations of CMV infections can be conveniently divided into manifestations associated with acute infection and virus replication and manifestations associated with chronic infections in which the relationship between disease and virus replication is not easily defined. Considerably more is known about acute infectious syndromes because acute CMV infections can be temporally related to specific symptoms and specific laboratory abnormalities. Infrequently, acute CMV syndromes can occur in presumably normal individuals and in these cases manifest as an infectious mononucleosis that is indistinguishable clinically from the infectious mononucleosis associated with Epstein-Barr virus infection [190,191]. Normal individuals with symptomatic infections often have increased viral burdens as measured by serologic responses compared with individuals with asymptomatic infections [53]. More commonly, acute CMV infections that result in symptomatic disease occur in immunocompromised hosts.

Generally, acute CMV syndromes that are associated with clinical disease often share several common characteristics, including (1) occurrence in hosts with altered cellular immunity, (2) poorly controlled virus replication, (3) multiorgan involvement, (4) end-organ disease secondary to direct viral cytopathic effects, and (5) clinical manifestations of disease correlated with virus burden. In patients with invasive CMV infections, such as those in allograft recipients, organ dysfunction and often disease course can be correlated with increasing virus burden [192–196]. There is usually not an absolute level of viral replication as measured by viral genome copy number in the peripheral blood that is predictive of the onset of an invasive infection and end-organ disease in all individuals. Rather, increasing levels of virus replication (genome copy number) seem more useful in the identification of individuals at risk for invasive disease and presumably reflect ongoing viral replication in the absence of efficient host control with an increasing risk of dissemination.

Chronic disease syndromes that have been associated with CMV include various chronic inflammatory diseases of older populations such as atherosclerotic vascular disease and vascular processes associated with chronic allograft rejection [197–206]. In addition, the progressive and late-onset hearing loss associated with congenital CMV infection could be considered in this same category [207–212]. The characteristics of populations experiencing these manifestations of CMV infection differ from the populations described previously and do not include hosts with obvious immune dysfunction. Most individuals have normal immunity, and allograft recipients experiencing chronic graft rejection may have increased immune responsiveness within the allograft.

Viral replication may be a prerequisite for disease, but the level of virus replication has not been correlated with disease. The course of the disease in animal models of CMV-associated vascular disease is ongoing inflammation that is enhanced and prolonged by the presence of CMV [213–217]. Inhibition of virus replication early in the course of infection in animal models has been shown to alter the course of disease dramatically, suggesting that virus must seed these areas and establish a persistent infection [215]. The presence of the virus in areas of inflammation increases the expression of soluble mediators of inflammation such as cytokines and chemokines, and in some cases, virus-infected cells actively recruit inflammatory cells including monocytes into the area of disease [218–220]. The bidirectional interactions between CMV and the host inflammatory response are unique and seem to favor virus persistence, viral gene expression, and probably virus dissemination.

### CYTOMEGALOVIRUS INFECTION AND CELL-ASSOCIATED VIREMIA

An important aspect of the pathogenesis of CMV infection is the route of infection and spread within the host. It is generally believed that virus is acquired either at mucosal sites (community exposures) or by blood-borne transmission, such as after blood transfusion or transplantation of an infected allograft. Understanding the pathogenesis of these types of infections requires an understanding of the mode of virus transmission and virus dissemination. It is believed that cell-free virus is responsible for community-acquired CMV infection based on recovery of virus from saliva and from cell-free genital tract secretions, but only limited data directly support this claim. More convincing evidence comes from studies in breast-feeding women, which have shown that infectious virus is present in the cell-free fraction of breast milk [130]. This finding suggests that cell-free virus can infect a mucosal surface. Animal models of CMV infection have most commonly used either intraperitoneal or subcutaneous inoculations; however, oral infection with cell-free murine CMV has been accomplished (Jonjic S, University of Rijeka, Rijeka, Croatia, personal communication).

After infection and local replication and amplification of virus titer in regional sites, the spread of CMV within an infected host is likely to be cell-associated based on findings from immunocompromised patients and studies in experimental animal models [103,221–225]. During infections of mucosal surfaces that occur after exposures in the community and blood-borne infections in transplant patients, the mode of spread and dissemination of the virus is likely the same, albeit with different kinetics and quantity of infected cells in the vasculature and infected organs. In all but the most severely immunocompromised patients, infectivity that can be shown in the blood compartment is most frequently associated with endothelial cells and polymorphonuclear leukocytes from the buffy coat fraction of peripheral blood [226–228].

Polymorphonuclear neutrophils (PMNs) cannot support virus replication, but have been shown to carry infectious virus and viral gene products [229,230]. It has been proposed that CMV-infected endothelial cells or fibroblasts can transfer infectious virus to PMNs, and these cells can transmit virus by a microfusion event between virus-containing vesicles and susceptible cells [229]. This mechanism has not been experimentally verified in animal models of CMV infection, but the role of PMNs in transmission of infectious CMV in vivo is consistent with clinical observations, and the correlation between CMV antigen-positive PMNs (antigenemia assay) and disseminated infection has been shown to be a diagnostic tool for the identification of patients at risk for invasive infection with CMV [231–236]. In addition, antigen-positive PMNs can be detected in normal hosts infected with CMV, but with a drastically reduced frequency compared with immunocompromised patients, suggesting that even in normal hosts PMNs may be a common mode of virus dissemination.

Other cells within the leukocyte fraction of peripheral blood cells support CMV persistence and transmit infectious virus, including monocyte/macrophages derived by differentiation of blood monocytes [223,237–239]. Granulocyte-monocyte progenitor cells have been proposed as sites of latency based on in vitro infections and can be detected as antigen-containing cells in immunocompromised patients with disseminated CMV infection [104–106,223,224,239–241]. In animal models of human CMV infection, an important role of myeloid precursors in the spread of murine CMV has been shown, including the role of virus-encoded chemokine-like molecules in chemoattraction of myeloid progenitor cells leading to dissemination of the virus from local sites of replication (see following section).

Macrophages derived from peripheral blood monocytes have been shown to harbor infectious CMV on stimulation with specific cytokines, including tumor necrosis factor-α [103,109,111]. Viral replication and expression of various early and late proteins can be shown in macrophages after infection with recently derived CMV clinical isolates. Together, these data have argued for a mechanism of in vivo spread that includes infection of circulating monocytes, which on entry into an organ undergo differentiation into a tissue macrophage that can support productive CMV infection [109].

Another cell lineage believed to be crucial for in vivo spread of CMV is endothelial cells in various microvascular beds. Endothelial cells have been shown to support CMV replication in vitro, and infection of these cells results in various cellular responses, including the release of cytokines and chemokines [237,242–249]. Lytic and nonlytic productive infections have been described suggesting that endothelial cells can respond very differently to infection [242,245,250,251]. Virus infection of endothelial cells is thought to be an initial step for infection of various tissues during CMV dissemination, and, likewise, endothelial cell infection seems to be crucial for hematogenous spread from infected tissue [229,237,249]. Early studies in transplant populations described viral antigen–containing endothelial cells circulating in the blood of viremic transplant patients [246,252,253]. These cells are believed to be infected endothelial cells that slough into the circulation, presumably secondary to local infection or inflammation or both. A similar role for endothelial cells in spread of CMV in the murine model and guinea pig CMV model has also been proposed [254]. Finally, in an elegant series of experiments, Sacher and coworkers [225] showed that replication of murine CMV within endothelial cells was essential for dissemination of this virus from sites such as the liver.

## VIRUS-ENCODED PATHOGENIC FUNCTIONS

To date, specific CMV-encoded virulence factors have not been identified. Early studies attempted to correlate differences in restriction fragment lengths of endonuclease-digested DNA of viral isolates from congenitally infected infants with clinical outcome. This genetic analysis proved too crude to allow identification of subtle changes in the viral genome. More recently, numerous studies have reported a possible linkage between polymorphisms in a gene encoding the major envelope glycoprotein gB and disease [255–258]. Almost all of these studies have failed to show any specific linkage between different gB genotypes and disease, and most recently, studies using other polymorphisms in several viral genes (UL11, UL18, UL40, UL73, UL74, UL144) have failed to establish a specific genetic linkage between a unique genotype and disease [259–267].

Although the explanation for the vast polymorphisms in CMV is unclear, several characteristics of CMV infections, including frequent reinfections with new strains of virus in exposed populations and recombination between strains of virus, are likely reasons for the variability in the nucleotide sequences of different viral isolates [160,187,257,268]. Differences in biologic behavior of CMVs exist, however, such that some strains exhibit extended tropism and can infect endothelial cells, macrophages, and epithelial cells in addition to permissive primary fibroblast cells. This extended tropism is a property of recently derived isolates of CMV, and after these viruses are repeatedly passaged through fibroblast cells, their extended tropism is quickly lost. It is believed that one or more viral genes are responsible for their extended tropism in vivo, and that without the selective pressure of replication in vivo, these genes are lost or mutated under in vitro conditions.

Specific genes that permit extended tropism in vitro have been identified and include the most well-characterized group encoded by the ORFs UL128 through UL131 [61,269,270]. In addition, the presence of numerous genes that modify the immune response to CMV raises the possibility that these genes encode a function that inhibits an innate response from cells such as macrophages that could also contribute to the extended tropism of some isolates. Other viral genes encode functional chemokine receptors (US28), viral cytokine-like molecules (vIL10, vIL-8), and viral antiapoptotic functions (vICA, UL37), all of which have been proposed to contribute to in vivo replication and virulence of CMV infections [271–280]. An observation suggested that different viral genotypes could be found in different tissues from infants with symptomatic congenital CMV infections who died in early infancy, a provocative finding that raises the possibility of as-yet-undefined viral functions that target different viruses to different tissues in vivo [281].

Although defining the function of viral genes in in vivo replication and spread of CMV has been difficult because of the restricted tropism of CMV to cells of human origin, much information has been gathered from studies in animal models. Using the mouse model of CMV infection, several laboratories identified specific viral genes that seemed to be required for efficient replication and spread in vivo [221,282–288]. Three viral genes encoded by m139, m140, and m141 ORFs of murine CMV have been shown to play a crucial role in viral replication in monocyte/macrophages, but have little to no effects on the replication of the virus in mouse fibroblasts [222,283,289–291]. The in vivo phenotype of viruses that lacked these genes indicated these genes were required for in vivo dissemination and spread of murine CMV [274,290]. To date, the mechanism that accounts for restricted replication in monocytes of murine CMV with deletions in these specific genes is unknown. The CMV gene that permits replication in monocyte/macrophages has not been definitively identified, but the murine CMV genes m139, m140, and m141 are homologous to a family of CMV genes (US22 gene family).

Another example of a viral gene that directly influences in vivo tropism and replication of CMV is the murine CMV gene *M45*. Endothelial cell tropism of murine CMV can be linked to the single viral gene *M45*, and it is believed that expression of this gene limits resistance of endothelial cells to murine CMV–induced apoptosis [254]. The deletion of the homologous reading frame in CMV (UL45) was not associated with the loss of endothelial tropism [292]. As noted earlier, the more recent findings that murine CMV dissemination required replication in endothelial cells provides additional evidence for the requirement of specific cellular tropism and in vivo behavior of CMVs.

Other genes in murine CMV encode functional chemokines, such as MCK-1, which exhibits activity similar to that of interleukin (IL)-8 in humans [222,274,289]. Studies in mice have suggested that the capacity of this gene product to recruit inflammatory cells into a site of virus replication is important for cell-associated virus spread within infected animals [222,274]. In the absence of this virus-encoded function, virus replication remains localized to the site of infection secondary to a failure to recruit and infect infiltrating inflammatory cells, limiting viral dissemination [222,274]. A functionally homologous viral gene in CMV, UL146, could influence the spread of CMV in vivo [293]. The protein encoded by UL146 is a secreted protein that seems to function as a CXCL chemokine (v-CXCL1) and can induce chemotaxis and degranulation of PMNs [293]. It has been postulated that this viral chemokine can recruit PMNs in vivo and promote CMV dissemination [274].

In severely immunocompromised hosts, such as AIDS patients with gastrointestinal and retinal disease secondary to disseminated CMV infection, neutrophil infiltration can be observed in the lamina propria and in the retina [294–296]. Infection of lamina propria macrophages with CMV in vitro results in the induction of IL-8 release from these cells, suggesting that CMV can induce IL-8 release and encode a viral IL-8-like molecule [274,297]. Such findings are consistent with the proposed mechanism of chemokine expression and CMV dissemination from sites of virus replication. This mechanism of dissemination is consistent with the histopathologic findings noted in severely immunocompromised patients; however, a neutrophil infiltrate is not an invariant feature of the histopathology of naturally acquired CMV infections, and interactions between other virus-encoded chemokines and chemokine receptors and peripheral blood leukocytes could contribute to virus dissemination.

Finally, more recent findings have shown that CMV engages toll-like receptors with resultant induction of proinflammatory cytokines and chemokine cascades [298]. This observation raises the possibility that virus infection alone can recruit cells such as monocytes and PMNs to sites of infection without the requirement of a specific viral chemokine [298]. Other viral genes likely induce host cell genes, which facilitate virus replication. Microarray and differential display experiments have shown that CMV infection induces the expression of cyclooxygenase-2, an enzyme required for prostaglandin synthesis and initiation of early steps of inflammation. Subsequent experiments have shown that if cyclooxygenase-2 activity is blocked, CMV replication is blocked [299]. Together, these experiments showed that a CMV-encoded gene could induce a cellular enzyme, which facilitated its replication possibly by increasing the inflammatory response to the infection. This host response presumably leads to the recruitment of inflammatory cells into the site of virus replication, promoting infection of infiltrating cells and virus spread.

CMV encodes four G-coupled protein receptor–like molecules in ORFs UL33, UL78, US27, and US28 [218,300–303]. The US28 gene encodes a G-coupled protein receptor that is constitutively activated and that can signal after interaction with chemokines, including RANTES, MCP-1, and fractalkine [218,303–305]. Reports have detailed possible roles for this molecule in the spread of CMV in vivo, including (1) as a chemokine sink to limit host cell chemotaxis to CMV-infected cells, (2) providing an antiapoptotic function, (3) recruitment of infected mononuclear cells to the sites of inflammation leading to dissemination of virus, and (4) perhaps even by binding of virus or virus-infected cells to chemokine-expressing endothelial

cells [303–307]. Arterial smooth muscle cells expressing US28 have been shown to migrate down chemokine gradients, providing a mechanism for the localization of CMV-infected cells to sites containing inflammatory cellular infiltrates [218].

Although the role of US28 in CMV-induced vascular disease has been well described and supported by in vitro models of smooth muscle cell migration, the importance of US28 in virus dissemination from local site of infection remains to be more completely defined. A more recent report has also provided evidence that US28 can respond to different chemokines depending on the resident cell infected by CMV, a finding that shows the adaptation of this virus to different host cells [305]. Together, these and other studies suggest that the large coding sequence of CMV encodes proteins that are essential for efficient replication and for spread within the infected animal, but probably has little, if any, function in in vitro replication of virus.

## HOST IMMUNITY AND PATHOGENESIS OF CYTOMEGALOVIRUS INFECTIONS

In normal hosts, innate and adaptive cellular immune responses can limit, but not prevent, the spread of CMV from secondary sites such as the liver and spleen. The roles of innate and adaptive cellular immune responses in the control of virus replication and spread to other sites have been extensively investigated in experimental animal models of CMV infection [308,309]. Increased levels of virus replication follow the loss of either group of cellular immune responses [309–313]. The importance of innate immunity, including natural killer (NK) cell responses and interferon responses, has been repeatedly shown in small animal models of human CMV infections [309,314]. The loss of virus-specific $CD4^+$ or $CD8^+$ cytotoxic T lymphocyte (CTL) responses is associated with uncontrolled virus replication and lethal disease in these models [310,312,313,315]. The role of virus-specific antibodies has also been defined in these models; these antibodies seem to contribute minimally to control of local virus replication, but play a key role in limiting bloodborne dissemination of the virus [316,317].

Antiviral antibody responses can control virus replication even in animals devoid of T lymphocytes, suggesting a critical role of this adaptive response to protective immunity to this virus [318]. A more recent study described the role of antiviral antibodies in limiting spread of murine CMV to specific organs, providing additional evidence for an important function of antiviral antibodies in control of virus dissemination [317]. These findings are of interest because in this model of CMV infection, virus spread is almost entirely by cell-associated virus and not cell-free virus, raising several questions, including regarding the mechanism by which antiviral antibodies restrict virus dissemination [221,284].

Consistent with the findings in experimental animal models, studies in immunocompromised human hosts have repeatedly shown that deficits in innate immunity and the loss of adaptive immune responses predispose the host to CMV infections and, depending on the severity of the immune deficit, can lead to invasive disease resulting in significant morbidity and mortality [178,319–326]. Several striking examples of the relationship between deficits in adaptive immunity and invasive CMV disease have been documented, including the development of pneumonitis in bone marrow and cardiac allograft recipients, prolonged CMV viremia and end-organ disease such as retinitis in AIDS patients with high viral (human immunodeficiency virus [HIV]) burdens and low $CD4^+$ lymphocyte counts, and in fetuses infected in utero.

Perhaps the most convincing evidence for the critical role of T-lymphocyte responses in host resistance to invasive CMV infection was provided in studies in bone marrow allograft recipients who received ex vivo expanded CMV-specific $CD8^+$ CTLs and were transiently protected from invasive CMV infection compared with a group of historical control patients, a finding that suggested that in this case CMV-specific $CD8^+$ effector cells served only to control virus replication, but not eliminate virus infection [321]. Another interesting finding from this study was that patients who failed to generate CMV-specific $CD4^+$ lymphocyte responses failed to generate long-term protection from CMV and developed invasive infections late in the course of their transplant [178,321]. This observation predated more recent studies that have shown that a $CD4^+$ response is required for maintenance of long-term immunity to infectious agents [327–331].

Effector cells and mediators of the innate immune response have also been shown to be critical for control of CMV infections. Although most studies have been done in murine models of CMV infections, loss of NK cell activity and invasive CMV infection has been reported [332–336]. More recent studies have also suggested that individuals with specific defects in innate immune responses, such as those associated with interferon responses, may be at increased risk for herpesvirus infections, although CMV infections have not been identified in these individuals [337,338]. As noted earlier, in murine models, NK cells and interferons have been shown to play a critical role in resistance to murine CMV infection and seem to represent an initial host response that can limit virus replication and spread during the development of more efficient effector functions of the adaptive immune system [339,340].

In contrast to the role of antiviral antibodies in limiting dissemination of murine CMV, the importance of antiviral antibodies in protective responses to human CMV infections remains controversial. Numerous studies have shown a correlation between antiviral antibody responses, particularly virus-neutralizing antibodies, and patient outcome [175,341–344]. In addition, studies in solid organ transplant patients given intravenous immunoglobulins containing anti-CMV antibodies have suggested that virus-specific antibodies can provide some degree of protection from invasive infections [345–350]. In other transplant populations, such as bone marrow allograft recipients, the efficacy of anti-CMV immunoglobulins remains unproven, and their use varies among different transplant centers [179,194,351–357]. Animal models other than mice have also indicated that antiviral antibodies could provide some degree of protection. In a

guinea pig model of congenital CMV infection, passive transfer of anti–guinea pig CMV (gpCMV) antibodies limited maternal disease and disease in infected offspring [317,358,359].

A study in pregnant women suggested that passive transfer of antibodies could limit intrauterine transmission of CMV, reduce the incidence of significant disease, and lead to resolution of existing CNS defects [360]. The results of this study were provocative and have stirred considerable debate in this field of investigation. Aspects of the study design, clinical outcome measures, and uncertainty surrounding mechanisms of action of the immunoglobulin preparations all have contributed to the lack of a consensus on the validity of the results of this study; however, these results have increased interest in similar therapeutic approaches. Available data would argue for a role of antiviral antibodies in limiting disease caused by CMV, and in the case of intrauterine infections, antiviral antibodies could freely pass into the fetal circulation and, if protective, could alter the outcome of intrauterine infections. The ramifications for the mode of action of antiviral antibodies can be readily appreciated when the design of prophylactic vaccines is undertaken.

## MODULATION OF HOST IMMUNE RESPONSE TO CYTOMEGALOVIRUS

Numerous laboratories have identified multiple viral genes whose products interfere with immune recognition and clearance of virus-infected cells. Table 23–7 describes some of these genes and their modes of action. The importance of these genes in the biology of CMV in vivo is not completely understood; however, animal models of CMV infection have allowed investigators to determine the importance of homologous genes during virus replication. The results from these studies have indicated that viral functions can actively interfere with virus clearance during acute infection in experimental animals [361–365]. Although a complete discussion of these viral genes and their mechanisms of immune evasion is beyond the scope of this chapter, several pertinent observations can be made regarding the importance of these viral genes in the pathogenesis of CMV infections.

First, these genes do not prevent recognition and control of CMV infections in normal hosts, as evidenced by the limited pathogenicity of this virus in normal individuals and in experimental animal models. Some investigators have argued that the phenotype of these viral genes can be appreciated only in immunocompromised hosts. The vast amount of literature describing the function of immune evasion genes has described studies carried out in experimental animals and during acute infection. In most studies, the function of these viral genes has been evaluated only in a few target organs, raising the question of whether some of these genes could be tissue-specific. Finally, other investigators have raised the question of whether these genes function to focus the immune response to a few viral antigens, restricting the available antigens for immune recognition. These viruses have committed a large amount of their genome to immune evasion functions (an estimated 20 genes in the genome of CMV), however, and many of these genes are conserved in animal and human CMVs. Studies in experimental animals have shown that immune evasion functions facilitate tissue-specific virus replication advantage in vivo [362,364,365]. These observations suggest that these genes almost certainly play a critical role in the biology of these viruses.

Immune evasion functions encoded by CMVs have been shown to interfere with innate immune responses and adaptive immune responses to virus-infected cells. In addition, mutations that result in mutation in viral structural proteins and in viral proteins recognized by the immune system also seem to allow escape from

**TABLE 23–7** Mechanisms of Cytomegalovirus Modulation of Host Immune Responses

| | Viral Gene | Mechanism |
|---|---|---|
| ***Innate Immune Responses*** | | |
| ↓ Intrinsic cellular response to virus infection | UL82 | Inhibits function of cellular Daxx function (degradation) |
| ↓ Interferon responses | UL83 (pp65) | ↓ IRFs, ↓ NF-κB |
| | TRS1 | ↓ PKR activity |
| ↓ NK cell activity | UL18 | MHC class I decoy |
| | UL40 | ↑ HLA-E expression |
| ***Adaptive Immune Responses*** | | |
| ↓ $CD8^+$, MHC restricted CTL | US2, US3, US11 | ↓ Class I expression |
| ↓ $CD4^+$ responses | US2 | HLA-DR degradation |
| | US6 | Blocks TAP transport |
| ↓ Antibody activity | TRL11 | Viral Fc receptor |
| Antigenic variation | UL73, UL55, UL75 | Loss of antibody binding |
| ***Cytokines, Chemokine Responses*** | | |
| Chemokine receptors (GPCRs) | US28, US27 | GPCR acts a sink for extracellular chemokines |
| Chemokines | UL21.5 | Chemokine receptor decoy inhibits RANTES |
| Cytokine | UL111a | Viral IL-10 |

immunologic control. Mutations in CMV viral genes encoding targets of dominant CD8+ CTL responses have been reported [366]. One murine CMV gene, m157, previously shown to activate NK responses through NK receptor Ly49H in strains of mice that were genetically resistant to murine CMV infection, acquired mutations within weeks of infection [367,368]. Viruses with mutations in m157 were shown to replicate to higher titers in strains of resistant mice. This mutational event seems to be secondary to immune selection because genetically susceptible strains of mice that do not use this NK cell activation pathway do not generate viruses with mutations in the m157 gene [368].

Antigenic variation in virion envelope glycoproteins that are targets of virus-neutralizing antibodies have been well described. Strain-specific neutralizing antibody responses to the envelope glycoprotein B have been described [369,370]. In addition, a study of the polymorphic envelope glycoprotein N suggested that immune selection was responsible for the variation in amino acid sequence of gN derived from different virus isolates [266,371]. CMVs, including human CMV, can evade immune recognition by various active mechanisms, such as immune evasion genes, and by more conventional strategies, such as loss of antigenic determinants or loss of key antigens required for activation and recognition by immune cells.

## PATHOGENESIS OF ACUTE INFECTIONS

Very early in the study of CMV infections, disease manifestations associated with congenital and perinatal CMV infections were related to the level of virus excretion, a marker for virus replication [372]. Subsequent studies in allograft recipients and in patients with AIDS have confirmed these findings and have consistently shown that increased levels of CMV replication in these patients was a key predictor of invasive disease. Unchecked virus replication and dissemination leads to multiorgan disease as illustrated by autopsy studies of neonates with congenital CMV infections, allograft recipients, and AIDS patients.

Studies in rhesus macaques infected with rhesus CMV have yielded results consistent with the proposed pathogenesis of human infection and provided a more detailed view of infection with this virus [373]. In these studies, virus given either intravenously or by a mucosal route resulted in blood-borne dissemination and widespread infection of numerous organs, including the liver and spleen [373]. The kinetics of the virus replication were different within the two groups with a lag in peak virus titers and liver infection noted in animals inoculated by a mucosal route. This result suggested that a local or regional amplification of virus was required after mucosal infection before blood-borne dissemination to the liver and spleen. This finding is consistent with experimental findings in guinea pigs and mice infected with CMVs [287,374–376].

The rhesus macaques that were inoculated by mucosal exposure remained asymptomatic and failed to exhibit clinical and laboratory abnormalities observed in animals given virus intravenously [373]. Together, these findings parallel clinical and laboratory findings in humans with infections from community exposures versus infections derived from blood products. Human infections after parenteral exposure to virus often exhibit similar clinical and laboratory abnormalities as described in these experimental animal models.

The dissemination of CMV from the liver and spleen to distal sites likely occurs in normal immunocompetent individuals and in immunocompromised hosts. It is also quite likely, however, that the quantity and duration of the viral dissemination are different in these two populations. In contrast to community-acquired CMV infections in normal adults, persistent viral DNAemia as detected by PCR is characteristic of populations with disseminated CMV infections, such as AIDS patients or infants with symptomatic congenital CMV infection [195,377–382]. It seems that the natural history of CMV infection includes local replication at mucosal sites followed by amplification of virus locally and possibly in regional lymphoid tissue and spread to the viscera such as liver and spleen. Virus replication in these organs further increases the quantity of viruses, and virus then spreads to distal organs and sites of persistence, such as the salivary glands and renal tubules.

From observations in humans and in experimental models of infection, symptomatic infection seems to be related to the level of virus replication in sites seeded by the primary viremia, such as the liver and spleen. It follows that parenteral exposure from sources such as contaminated blood is associated with symptomatic infections because a larger viral inoculum is delivered to organs such as the liver, often in the absence of a developing immune response that would normally be present after infection of a mucosal surface. The duration of virus replication is likely represents a composite of the level of dissemination and the efficiency of the host immune response in the control of replicating CMV.

## PATHOGENESIS OF CENTRAL NERVOUS SYSTEM INFECTIONS IN CONGENITALLY INFECTED INFANTS

The disease manifestations of congenital CMV infections include manifestations seen in adult immunocompromised hosts with disseminated CMV infections, such as hepatitis and, infrequently, pneumonitis and adrenalitis [383–385]. Unique to congenital CMV infection is the presence of CNS disease, a manifestation rarely seen even in the most immunocompromised allograft recipients. CMV encephalitis has been reported in patients with AIDS, but this disease can be distinctly different clinically and pathologically from CMV infection of the CNS associated with intrauterine infection [383,386]. CNS involvement in infants with congenital CMV infections often is associated with ongoing disease, such as progressive hearing loss during the first few years of life, at a time when there is no apparent progression of structural damage in the CNS [207–211, 387–393].

The pathogenesis of CMV CNS infection in the developing fetus is poorly understood for several reasons, including the lack of a sufficiently large number of cases from autopsy studies. In addition, there are no well-developed animal

models of CNS infection associated with congenital CMV infection. The murine CMV model is useful for the study of many aspects of CMV infection, but congenital infection with murine CMV does not occur in mice. The other widely employed small animal model, the guinea pig, can be used to study intrauterine infections, and early reports suggested that CNS infections developed in these animals [394,395]. The usefulness of this model for studying CNS infection has not been defined, however, and because only a few observational studies have been reported, it has been difficult to assess its value as an informative model. The rhesus macaque offers perhaps the most relevant model for the study of CMV CNS infections for several obvious reasons, including the similarities in brain development shared between macaques and humans. In addition, rhesus CMV is more closely related to CMV than the rodent and guinea pig CMVs. This model is expensive, however, and these experimental animals are in limited supply secondary to their use in studies of HIV. For these reasons, our understanding of CNS infection with CMV remains limited.

Infection of the developing CNS is associated with many structural abnormalities that are dependent on the age of fetus at the time of CNS infection. Imaging studies of living infants and children with congenital CMV infections and clinical findings consistent with CNS disease have been informative. Commonly noted abnormalities include periventricular calcifications, ventriculomegaly, and loss of white-gray matter demarcation [396–398]. More refined imaging studies have detailed loss of normal brain architecture with loss of normal radial neuronal migration and cerebellar hypoplasia [399–408]. Limited autopsy studies have confirmed these imaging abnormalities and have shown the presence of inflammatory infiltrates in the parenchyma of the brain [397]. This latter finding is consistent with the presence of increased protein and inflammatory cells in spinal fluid obtained from congenitally infected infants with CNS disease. Together, these findings argue for a pathogenic spectrum that likely includes lytic infection of neuronal progenitor cells in the subventricular gray area, vasculitis with loss of supporting vessels in the developing brain, and meningoencephalitis with release of inflammatory mediators.

It is unclear why the fetal and newborn brain are susceptible to CMV infection in contrast to the adult brain; however, findings from experimental models suggest that the developing cells of the CNS are particularly susceptible to the lytic or possibly the apoptotic effects of CMVs [409–411]. In animal models, including mice and rhesus macaques, infection of the developing CNS results in widespread lytic virus replication, including neuronal progenitor cells of the subventricular gray area and endothelium [412–414]. Lytic virus replication in this area would lead to loss of normal neuronal development, radial migration, and vascularity of the developing brain. Extravasation of blood from damaged microvasculature would lead to calcifications that are prominent findings in imaging studies of CMV-infected newborn infants. Virus could spread through the ventricular system and infect additional areas of the subventricular germinal zone.

The more severe manifestations of CMV CNS infection can be explained by lytic virus infection of neuronal progenitor cells, glial cells in the CNS, and destruction of supporting vasculature. As indicated previously, intracerebral inoculation of fetal rhesus macaques with rhesus CMV results in similar findings as described in severely affected human infants and suggests that if CMV enters the CNS early in development, significant structural damage ensues.

Other infants infected in utero with CMV exhibit clinical findings consistent with CNS involvement, including developmental delays and loss of perceptual functions, but do not have structural damage of the brain that can be detected by routine imaging techniques. At least one autopsy series suggested that affected infants without calcifications can have neuronal migration deficits manifest as pachygyria and other abnormalities such as cerebellar hypoplasia [397,404,408]. The mechanisms leading to loss of normal architecture are unknown, but could be related to ongoing inflammation in the CNS secondary to intrauterine meningoencephalitis. Various inflammatory mediators have been shown to cause loss of neuron and supporting cell function and can modify vascular permeability and endothelial function. Evidence from experimental animal models has suggested that cytokines and chemokines may directly influence neuronal radial migration [415,416]. Ongoing inflammation may result in loss of normal brain architecture secondary to delayed or absent radial migration of neurons destined for the cerebral cortex [417].

## PATHOGENESIS OF HEARING LOSS ASSOCIATED WITH CONGENITAL CYTOMEGALOVIRUS INFECTION

Hearing loss is one of the most common long-term sequelae of congenital CMV infection, and its pathogenesis is perhaps the least understood of any manifestation of CMV infection. As discussed in preceding sections, hearing loss can range from mild to profound, can be unilateral or bilateral, and can develop or progress after the perinatal period. It is possible that hearing impairment may represent a common outcome resulting from CMV infections in different parts of the auditory apparatus or, alternatively, resulting from infection in different stages in the development of the auditory system.

Besides the potential complexity of the disease, several other reasons likely contribute to the lack of understanding of the pathogenesis of hearing loss that follows congenital CMV infection. One of the most apparent is the lack of adequate histopathologic examinations of affected tissue from infected infants. A literature review revealed that only 12 temporal bones from congenitally infected infants have been studied and described in the medical literature [418]. In addition, most of the studies were done without the aid of modern techniques of virus and viral antigen detection and relied almost entirely on conventional histologic examinations. These limitations together with the lack of adequate information on the maternal and fetal infection have resulted in the lack of solid clues to the possible mechanisms of virus-induced damage to the auditory system.

Hearing loss in CNS infections in adults with AIDS or transplant infections is rare and not well described, presumably because these infections differ significantly from

congenital CMV infection in the extent of CNS involvement and the underlying diseases and treatment that lead to CNS infection in these immunocompromised patients, and perhaps most importantly, congenital CMV infections occur during development. Finally, animal models of CMV hearing loss have been developed and have provided some information regarding selected aspects of the hearing loss associated with CMV. They have generally failed to recapitulate the disease, however, and in some cases early findings have been difficult to reproduce. More recently, a murine model of perinatal (congenital?) CMV infection and hearing loss has been developed that could provide some insight into the pathogenesis of the human disease (Bradford R, Britt W, unpublished).

Strauss [419,420] provided a comprehensive review of temporal bone pathology in infants with congenital CMV infection. The specimens in this series were from infants who died between 3 weeks and 5 months of age. A single case report of a 14-year-old patient with severe neuromuscular sequelae resulting from congenital CMV was described [421]. Findings in the inner ear, cochlea, vestibular system, and auditory and vestibular neural structures were described in all patients. Five of the original nine specimens had evidence of endolabyrinthitis, and virus was isolated from the endolymph in three of the nine specimens [420]. Viral antigen was detected by immunofluorescence in two cases in which routine histology failed to show viral inclusions [207]. Cochlear and vestibular findings were variable and ranged from rare inclusion-bearing cells in or adjacent to the sensory neuroepithelium of the cochlea or vestibular system to more extensive involvement of the nonsensory epithelium. Routine histology failed to detect viral inclusions in the auditory and vestibular neural structures, but viral antigens were detected in the spiral ganglion when specimens were examined by immunofluorescence [207]. Inflammatory infiltrates were minimal and reported in only three patients in this series [420]. Perhaps the most interesting results were those reported in the examination of tissue from the 14-year-old patient with extensive sequelae from congenital CMV infection. In this patient, extensive cellular degeneration, fibrosis, and calcifications were observed in the cochlea and vestibular systems [421].

Several generalizations can be made from these limited data. First, in all but two of these cases, virus, viral antigens, or histopathologic findings consistent with virus infection were present in the cochlea or vestibular apparatus. These findings indicate that virus replication could have occurred in the sensory neuroepithelium and nonsensory epithelium and that cellular damage could be explained by a direct viral cytopathic effect. In addition, viral-induced damage can also result from bystander effects secondary to immune-mediated cytopathology. CMV could induce loss of sensory neuroepithelium in the absence of direct infection of the sensory neuroepithelium, but secondary to infection of supporting epithelium followed by host immunopathologic responses. An inflammatory infiltrate was seen in only three of nine specimens, however, an unexpected finding based on the role that the inflammatory response is thought to play in CMV end-organ disease in other patient populations.

It is well documented that infants with congenital CMV have a delay in the development of immunologic responses to CMV, and it could be argued that findings in the cochlea and vestibular apparatus are consistent with the ineffectual immune responses of congenitally infected infants. An alternative and not exclusive possibility is that infection of the inner ear structures is a late, and in some cases a postnatal, event. The relationship between susceptibility of cells of the sensory neuroepithelium and supporting epithelium to infection with CMV and their developmental status is unknown. These cells could be resistant to CMV infection until late in development. In this case, findings from specimens of the above-described autopsy series may reflect recent infection before host inflammatory responses. Such an explanation is inconsistent, however, with the course of fetal CMV infection in other parts of the CNS in most of the patients included in autopsy studies. A third possibility is that hearing loss in some infected infants is related to alterations in the neural networks leading from the cochlea to the eighth cranial nerve. Finally, the finding of extensive degenerative changes together with fibrosis and calcifications in the temporal bones from the oldest patient presumably reflects the natural history of CMV labyrinthitis and, depending on the rate at which these changes develop, could also explain the progressive nature of hearing loss associated with congenital CMV infection.

The loss of neuroepithelium, secondary to either direct virus-mediated damage or host-derived inflammation followed by fibrosis, would be consistent with the profound hearing impairment that develops in some children with congenital CMV infection. Findings in experimental animal models have indicated that exaggerated deposition of extracellular matrix is part of the inflammatory response in the inner ear, and this host response possibly leads to the ossification that is observed in animals inoculated directly into the labyrinth with CMV [422,423].

Studies in animal models have provided limited insight into the pathogenesis of hearing loss after congenital CMV infection. Small animal models have provided some information and have mirrored findings in humans. Virus and inflammation are required for the development of pathology in the inner ear. A study in guinea pigs showed that virus infection in immunocompromised animals was not associated with the typical pathologic findings of virus infection in normal animals [422]. Similarly, blocking virus replication with antiviral compounds or pretreating animals with virus-neutralizing antibodies limited the development of inner ear pathology [424–429]. From the available studies, the pathogenesis of hearing loss associated with congenital CMV infection requires virus replication and a host immune response. Interrupting either virus replication or the local host inflammatory response could offer some therapeutic benefit to these patients.

## NATURE OF MATERNAL INFECTION

The nature of the maternal infection is a major pathogenetic factor for congenital CMV infection. Primary infections are more likely to be transmitted to the fetus and are thought to be more frequently associated with fetal

damage than recurrent infections [430]. With primary CMV infection, as in other infections during pregnancy, there seems to be some innate barrier against vertical transmission [121,122,212,431,432]. Intrauterine transmission after primary infection occurs in 30% to 40% of cases [121,212]. Current information suggests that gestational age has no apparent influence on the risk of transmission of CMV in utero [121,122,212,431,433]. With regard to the role of gestational age on the expression of disease in the fetus and offspring, infection at an earlier gestational age has been associated with more severe disease and worse outcome [122,212,431,432,434]. Definition of the interval in pregnancy in which maternal seroconversion occurred does not define a similar time of fetal infection, however.

Congenital infection may also result from recurrences of infection [121,153–155,157,158,435–440]. The term *recurrence* is used here to represent either reactivation of infection or reinfection with the same or a different strain of CMV during pregnancy. Despite the inability of maternal immunity to prevent transmission of this virus to the fetus, congenital infections that result from recurrent infections are thought to be less likely to produce clinical evidence of disease in infected offspring than those resulting from primary infections [121,430]. The relationship between primary infection and clinically apparent congenital infection in offspring was challenged initially by studies from Sweden and more recently in the United States and other regions of the world [157,158,436–444]. These studies have shown that clinically apparent congenital infections are frequently observed in infants infected after a recurrent maternal infection and that long-term sequelae such as hearing loss can be present in such infants. Clinical experience continues to suggest, however, that severe multiorgan disease in congenitally infected infants should suggest the possibility of primary maternal infection.

The risk of congenital CMV infection resulting from a recurrence of infection during pregnancy ranges from 1.5% for a U.S. population of low socioeconomic background to 0.19% for women of middle or upper socioeconomic background from the United States, Great Britain, or Sweden [121,212,441,445]. In the developing world, studies in maternal populations with near-universal seroimmunity have shown congenital infection rates of 1% to 2%, and infants with clinically apparent infections and infants who develop long-term sequelae from congenital CMV infections have been described in these populations [153,157,158,439,446].

In recurrent infection, it is likely that preexisting maternal immunity could alter the parameters of CMV in the mother and developing fetus at least to some extent. It is unknown if preexisting cellular immunity is more important than humoral immunity; however, maternal IgG antibodies are transmitted to the fetus and at a first approximation could alter the virologic parameters of fetal infection. Several cases of symptomatic congenital infection have been reported in offspring of women after therapeutic immunosuppression, women with lupus or AIDS, and women with intact immune systems, suggesting that altered maternal immunity either from immunosuppression or from an inability to recognize a recurrent maternal infection (reinfection) can lead to fetal infection and disease [441,447–452].

In the rhesus macaque model of CMV neuropathogenesis, a direct infection of the developing rhesus fetus can lead to disease even in the presence of maternal T-lymphocyte and antiviral antibody immunity to the virus [413]. This result would argue that when virus enters the fetus, a critical balance between fetal immunity, maternal immunity that can be transferred to the fetus, and viral inoculum determines the extent and severity of fetal infection. Such a complex relationship between virus and immunity suggests that analysis of specimens derived from human natural history studies would likely provide only a limited insight into this intrauterine infection.

## PERINATAL INFECTION

Naturally acquired perinatal CMV infections result from exposure to infected maternal genital secretions at birth or to breast milk during the first months of postnatal life [130,131,453,454]. The presence of CMV at these two sites may be the result of either primary or recurrent maternal infection. Iatrogenic CMV infections are acquired predominantly from transfusions of blood or blood products and, in the past, banked breast milk from CMV-infected donors. Exposure to CMV in the maternal genital tract can result in a 30% to 50% rate of perinatal infection. The transmission from mother to infant through breast milk occurs in 30% to 70% if nursing lasts for more than 1 month [130,131,165,455–459]. After ingestion of the virus, CMV infection is presumably established at a mucosal surface (buccal, pharyngeal, or esophageal mucosa) or in the salivary glands, for which CMV is known to have a special tropism. Perinatal CMV infections occasionally and congenital CMV infections rarely have been associated with pneumonitis; in early reports, CMV pneumonia was reported to account for significant mortality in congenitally infected infants [173].

Transmission of CMV by blood transfusion is more likely to occur when large quantities of blood are transfused, providing some clues as to the nature of persistence of CMV in cells of the blood and an indirect assessment of the frequency of CMV-infected cells in the blood. The failure to isolate CMV from the blood or blood elements of healthy seropositive blood donors suggests that the virus exists in a latent state, presumably within leukocytes. It has been suggested that CMV reactivates after transfusion when infected cells encounter the allogeneic stimulus. CMV genomes are activated when transfused to a recipient, particularly if immunologically immature or deficient.

## PERSISTENT VIRAL EXCRETION

Congenitally and perinatally acquired CMV infections are characterized by chronic viral excretion [384]. Virus is consistently shed into the urine for 6 years or longer and into saliva for 2 to 4 years. Not only does excretion persist much longer in congenitally infected infants than in infected older children and adults, but also the quantity of virus excreted is much greater. Even asymptomatic, congenitally or perinatally infected infants excrete quantities of virus that usually exceed quantities detectable in seriously ill

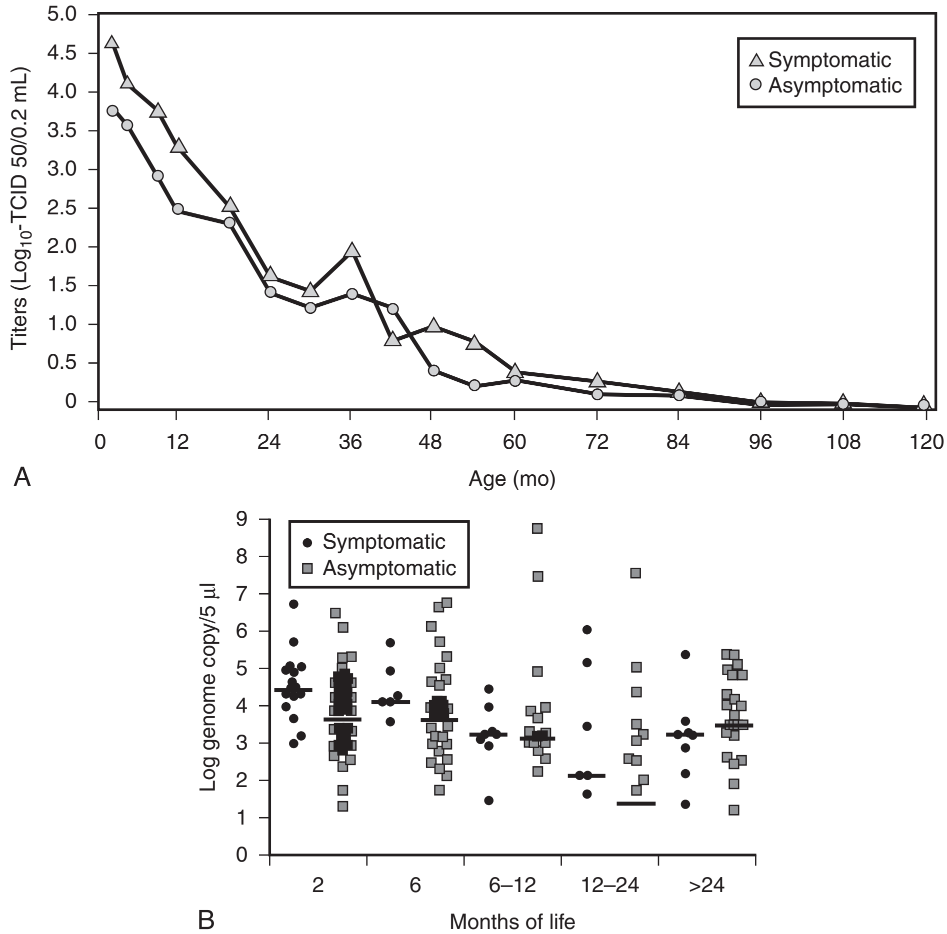

**FIGURE 23–3** **A,** Viral load detected by urine excretion of infectious virus in infants with symptomatic and asymptomatic congenital human cytomegalovirus infection as a function of age. Titers are expressed as log of tissue culture infectious doses (TCID) in which 50% of wells contained virus. **B,** Genomic copies of human cytomegalovirus in blood from congenitally infected infants with symptomatic (●) and asymptomatic (■) infections. Median values are designated by *red horizontal bars*.

immunocompromised older patients by 1 to 2 logs. As illustrated in Figure 23–3A, the highest quantities of virus are excreted during the first 6 months of life. Infants with symptomatic congenital CMV infection excrete significantly larger amounts than infants with asymptomatic congenitally or perinatally acquired infections. Similar results have been obtained when peripheral blood of congenitally infected infants has been analyzed by quantitative polymerase chain reaction (PCR) (Fig. 23–3B) [460]. A relationship has been identified between the viral DNA copy number in peripheral blood and long-term outcome suggesting that monitoring congenitally infected infants by this assay could identify infants at risk for sequelae and select a population of congenitally infected infants that could be considered as potential candidates for treatment with antiviral agents (see following sections) [460,461].

## PATHOLOGY

Early reports of histopathologic changes associated with CMV infections relied on a demonstration of classic changes characterized by cytomegaly and nuclear and cytoplasmic inclusions. The distinctive features include large cells 20 to 35 mm in diameter with a large nucleus containing round, oval, or reniform inclusions. These large inclusions are separated from the nuclear membrane by a clear zone, which gives the inclusion the so-called owl's eye appearance. The inclusions within the nucleus show DNA positivity by histochemical staining, whereas the cytoplasmic inclusions contain carbohydrates, as evidenced by periodic acid–Schiff positivity. The cytoplasmic inclusions vary from minute dots to distinct rounded bodies 3 to 4 mm in diameter. The cytoplasmic inclusions are usually aggregated opposite to the eccentrically placed inclusion-bearing nucleus and seem to represent a cytoplasmic site of virus assembly [462]. The classic CMV inclusion-bearing cell may be only scattered throughout involved tissue and missed by routine sectioning. This finding has been confirmed when more refined techniques, such as in situ DNA hybridization and immunofluorescence using CMV-specific monoclonal antibodies, have been used to define the extent of infection with CMV in immunocompromised patients.

### COMMONLY INVOLVED ORGAN SYSTEMS

Disseminated disease can occur in the infected fetus and the congenitally infected infant. CMV can cause a multisystem disease in which almost all major organ systems are involved [383].

## Central Nervous System

Involvement of the CNS is perhaps the most important consequence of fetal infection with CMV. Most descriptions of the pathology of CNS infection are relevant only to infants with severe CID, which is occasionally fatal [383,397,463–465]. In most infected infants, the infection can be described grossly as focal encephalitis and periependymitis. Encephalitis can involve cells of the gray and the white matter and cells within the choroid plexus. Inclusion-bearing cells have been identified in neurons, glia, ependyma, choroid plexus, meninges, and vascular endothelium and in cells lying free in the ventricles. Rarely, inclusion-bearing cells have been identified in the cerebrospinal fluid [466]. Resolution of acute encephalitis leads to gliosis and calcification. Previous descriptions have emphasized the periventricular location of calcifications; however, these lesions can be located anywhere in the brain [398,404,408].

CMV has been isolated on a few occasions from cerebrospinal fluid, and PCR has been used more recently to show CMV in the cerebrospinal fluid [467,468]. The only other patients with a significant incidence of CMV encephalitis are individuals with HIV/AIDS. Infection of the CNS by CMV is well described in these patients and has been characterized as ventriculoencephalitis in which the virus is thought to spread through the ventricular system and result in widespread disease in the periventricular neuroepithelium and a second more common form described as a focal encephalitis [386].

CMV infection of structures of the hearing apparatus has been described as noted in the previous sections. Viral inclusion-bearing cells and viral antigen–containing cells can also be found within structures of the inner ear, including the organ of Corti, and in epithelial cells of striae vascularis of the cochleae [207,469–471]. Finally, involvement of the eye, including chorioretinitis, optic neuritis, cataract formation, colobomas, and microphthalmos, has been shown [207,472–474]. The histopathologic changes associated with retinitis begin as an acute vasculitis that spreads into the choroid through the vascular basement membrane. CMV has been isolated from fluid of the anterior chamber of the eye [475]. Anecdotal cases of cataracts have been described in congenitally infected infants. Finally, the clinical findings of infants with CMV chorioretinitis differ from the clinical findings of HIV/AIDS patients with retinitis in that level of retinal involvement is often less; the cellular infiltrate and retinal edema are also limited when the findings in these patients are compared with patients with HIV/AIDS. Chorioretinitis in congenitally infected infants has been associated with an increased risk of long-term cognitive disorders in congenitally infected infants [476].

## Liver

Involvement of the liver is common in congenital CMV infections. Clinical evidence of hepatitis as manifested by hepatomegaly, elevated levels of serum transaminases, and direct hyperbilirubinemia is frequently seen in infants with symptomatic congenital infections. Pathologic descriptions of hepatic involvement include mild cholangitis with CMV infections of bile duct cells, intralobular cholestasis, and obstructive cholestasis secondary to extramedullary hematopoiesis [383]. Liver calcifications have been detected radiologically in infants with congenital infections [477,478]. Clinical and laboratory evidence of liver disease eventually subsides in surviving infants, and only anecdotal cases of cirrhosis have been reported.

## Hematopoietic System

Hematologic abnormalities, including thrombocytopenia, anemia, and extramedullary hematopoiesis, are common in symptomatically infected infants, but these abnormalities almost invariably resolve within the 1st year of life. The exact mechanism accounting for these disturbances is uncertain, although congestive splenomegaly resulting in platelet and red blood cell trapping must play some part in the overall process. Significant splenomegaly is common, and congestion, extramedullary hematopoiesis, and diminished size of lymphoid follicles can be seen histologically.

In congenital CMV infections, thrombocytopenia may persist for several months or years, with or without petechiae. Anemia is another feature of symptomatic congenital CMV infection. The presence of indirect hyperbilirubinemia, extramedullary hematopoiesis, and erythroblastemia indicates active hemolysis, but mechanisms that account for these findings have not been well described.

## Kidneys

Macroscopically, the kidneys show no alterations. Microscopically, inclusion-bearing cells are commonly seen, especially in the cells lining the distal convoluted tubules and collecting ducts [383,479]. Affected cells may desquamate into the lumens of the tubules and appear in the urine sediment. Inclusions can be found occasionally in Bowman capsules and proximal tubules. Mononuclear cell infiltration may be present in the peritubular zones of the kidney.

## Endocrine Glands

Secretory cells of endocrine glands commonly contain typical CMV inclusions. In the pancreas, the endocrine and the exocrine cells are affected [383]. Some reports describe intralobular or periductal mononuclear infiltration, suggesting focal pancreatitis. There is no credible association between congenital CMV infection and the development of diabetes mellitus. CMV inclusion-bearing cells have been documented in follicular cells of the thyroid, the adrenal cortex, and the anterior pituitary.

## Gastrointestinal Tract

The salivary glands are commonly involved in congenital and perinatal CMV infections. There are no reliable figures, however, on the frequency of involvement because the examination of the salivary glands is not always part of autopsies [383]. CMV inclusions have also been described in the mucosal surfaces of the esophagus, stomach, and intestine and in the vessels of ulcerative intestinal lesions [383,480].

## Lungs

Pulmonary CMV lesions are similar in newborn and adults. Microscopically, most inclusion-bearing cells are alveolar cells that lay free in terminal air spaces. Generally, there is little inflammatory reaction; however, in the more severe cases, focal interstitial infiltration by lymphocytes and plasma cells can be found.

## Placenta

Abnormalities are present in the placentas of most patients with symptomatic CMV infection and are infrequent with subclinical infections [481–485]. CMV DNA can be detected frequently in the decidua and placenta of seropositive women, even though the rate of congenital infection in this population is on the order of 1%, a finding that supported the hypothesis that the placenta represents a barrier for fetal infection [486–488]. Previous studies have suggested that placentas are not remarkable in size or macroscopic appearance; however, a more recent study suggested placenta enlargement in some women who delivered infected infants [489].

The most specific feature histologically is the presence of inclusion-bearing cells, which may be found in endothelial cells, in cells attached to the capillary walls, or in Hofbauer or stromal cells [482,484]. Other lesions include focal necrosis, which in early gestation shows sparse infiltration by lymphocytes, macrophages, and a few plasma cells. The early lesions manifest as foci of necrosis of the stroma and occasionally of the vessels of the villi. The focus of necrosis is later invaded by inflammatory cells, histiocytes, and fibroblasts. At later gestational ages, these focal lesions become densely cellular, with plasma cells predominating over lymphocytes. Deposition of intracellular and extracellular hemosiderin can be found in stem and terminal villi and is presumably the result of fetal hemorrhage during the necrotizing phase or of maternal intervillous thrombosis. Calcification within villi or on basement membranes has also been described as a late manifestation of placental CMV infection.

In recent years, there has been increased interest in understanding the role the placenta plays in congenital CMV infection [481,490]. In vitro systems have been developed to examine interactions between CMV and the placenta. Studies from these systems have uncovered a complex relationship between maternal immunity and the likelihood of CMV replication in distinct areas of the placenta and the decidua [249,481,491]. In addition, other investigators have noted that the immune tolerance of the placenta could limit efficient clearance of virus. The placenta produces the immunosuppressive chemokine IL-10, and expression of HLA-G in the placenta is thought to limit NK cell activity [492–497].

These findings have led investigators to suggest that CMV replication in the placenta is poorly controlled and that transmission to the fetus occurs after infection of cytotrophoblasts [491]. More recent studies have suggested that CMV can dysregulate the expression of proteins essential for normal placentation and that CMV infection of the placenta can lead to placental insufficiency and intrauterine growth restriction and potentially other effects on the fetus [481]. This proposed mechanism of disease is consistent with a potential immunomodulatory role of passively transferred intravenous immunoglobulin in pregnant women [360]. A study in the guinea pig model of congenital infection that showed the protection from perinatal CMV disease by a recombinant virus expressing a guinea pig CMV envelope glycoprotein could be interpreted as reflecting the capacity of antiviral immunity to limit the placental insufficiency induced by guinea pig CMV infection in these pregnant animals [498].

# CLINICAL MANIFESTATIONS

## CONGENITAL INFECTION

Approximately 10% of the estimated 44,000 infants (1% of all live births) born annually with congenital CMV infection in the United States have signs and symptoms at birth that are consistent with the diagnosis of a congenital infection. Only half of these symptomatic infants have typical generalized CID, characterized mainly by the clinical manifestations listed in Table 23–8 [212,385,430,499,500]. Another 5% of these infants present with milder or atypical involvement, and 90% are born with subclinical congenital infection. Because early studies emphasized only symptomatic infections, congenital CMV was considered a rare and often fatal disease. In the early reports, many patients were referred to the investigators because of

**TABLE 23–8** Clinical and Laboratory Findings in 106 Infants with Symptomatic Congenital Cytomegalovirus Infection in the Newborn Period

| Clinical/Laboratory Abnormality | Positive/Total Examined (%) |
|---|---|
| Prematurity (<38 wk) | 36/106 (34) |
| Small for gestational age | 53/106 (50) |
| Petechiae | 80/106 (76) |
| Jaundice | 69/103 (67) |
| Hepatosplenomegaly | 63/105 (60) |
| Purpura | 14/105 (13) |
| Neurologic findings (one or more of the following) | 72/106 (68) |
| Microcephaly | 54/102 (53) |
| Lethargy/hypotonia | 28/104 (27) |
| Poor suck | 20/103 (19) |
| Seizures | 7/105 (7) |
| Elevated alanine aminotransferase (>80 U/L) | 46/58 (83) |
| Thrombocytopenia | |
| $<100 \times 10^3/mm^3$ | 62/81 (77) |
| $<50 \times 10^3/mm^3$ | 43/81 (53) |
| Conjugated hyperbilirubinemia | |
| Direct serum bilirubin >4 mg/dL | 47/68 (69) |
| Hemolysis | 37/72 (51) |
| Increased cerebrospinal fluid protein (>120 mg/dL)* | 24/52 (46) |

abnormalities in normal development; this led to a selection bias of a group of patients at a higher risk for persistent abnormalities and neurologic damage. The use of more sensitive and specific methods of diagnosis, particularly viral isolation and newer methods of rapid virus detection, has allowed prospective longitudinal studies of newborns with symptomatic and asymptomatic congenital CMV infections. These studies have resulted in a more accurate understanding of the infection and its clinical spectrum.

## Symptomatic Infection

### *Acute Manifestations*

Clinically apparent infections or CID is characterized by involvement of multiple organs, in particular, the reticuloendothelial system and CNS, with or without ocular and auditory damage. Weller and Hanshaw [501] defined the abnormalities found most frequently in infants with symptomatic congenital infection as hepatomegaly, splenomegaly, microcephaly, jaundice, and petechiae. As shown in Table 23–8, petechiae, hepatosplenomegaly, and jaundice are the most frequently noted presenting signs.

In addition, the magnitude of the prenatal insult is reflected by the occurrence of microcephaly with or without cerebral calcification, intrauterine growth restriction, and prematurity.* Inguinal hernia in boys and chorioretinitis with or without optic atrophy are less common. Clinical findings occasionally include hydrocephalus, hemolytic anemia, and pneumonitis. Among the most severely affected infants, mortality rates may be 10% to 30% [173,385]. Most deaths occur in the neonatal period and are usually due to multiorgan disease with severe hepatic dysfunction, bleeding, disseminated intravascular coagulation, and secondary bacterial infections. When death occurs after the 1st month but during the 1st year, it is usually secondary to severe failure to thrive, possibly owing to ongoing liver disease and dysfunction. Death after the 1st year is usually restricted to severely neurologically damaged children and is due to malnutrition, aspiration pneumonia, and infections associated with neurologically impaired infants.

#### Hepatomegaly

Hepatomegaly, along with splenomegaly, is probably the most common abnormality found in the newborn period in infants born with a symptomatic congenital CMV infection [503]. The liver edge is smooth and nontender and usually measures 4 to 7 cm below the right costal margin. Liver function tests are often abnormal and reflect hepatocellular dysfunction and cholestasis. The persistence of hepatomegaly is variable. In some infants, liver enlargement disappears by age 2 months. In others, significant enlargement persists throughout the 1st year of life. Hepatomegaly extending beyond the first 12 months of life is an uncommon finding in infants with CID.

*References [86,368–371,385,396,398,404,408,431,444,502].

#### Splenomegaly

Enlargement of the spleen exists to a greater or lesser degree in all the common human congenital infections and is especially frequent in congenital CMV infections [385]. Splenomegaly may be the only abnormality present at birth. In some instances, splenomegaly and a petechial rash coexist as the only manifestations of disease. Occasionally, the enlargement is such that the spleen may be felt 10 to 15 cm below the costal margin. Splenomegaly usually persists longer than hepatomegaly.

#### Jaundice

Jaundice is a common manifestation of congenital CID. The pattern of hyperbilirubinemia may take several forms, ranging from high levels on the 1st day to undetectable jaundice on the 1st day with gradual elevation of the bilirubin level to clinically apparent jaundice. The level of jaundice in the early weeks of life may fluctuate considerably [385]. In some instances, jaundice is transient, beginning on the 1st day and disappearing by the end of the 1st week. More often, jaundice tends to persist beyond the time of physiologic jaundice. Transient jaundice may occasionally occur in early infancy with pronounced elevation of bilirubin levels during the 3rd month. Bilirubin levels are elevated in the direct and the indirect components. Characteristically, the direct component increases after the first few days of life and may constitute 50% of the total bilirubin level. Hepatic transaminases are elevated, but abnormalities in coagulation secondary to liver disease are infrequently observed.

#### Petechiae and Purpura

There is evidence from experimental animal models that CMV has a direct effect on the megakaryocytes of the bone marrow that results in a depression of the platelets and a localized or generalized petechial rash, although similar studies have not been done in humans infected with CMV. In some patients, the rash is purpuric (Fig. 23–4), similar to that observed in the expanded rubella syndrome.

In contrast to rubella, pinpoint petechiae are a more common manifestation. These petechiae are rarely present at birth, but often appear within a few hours thereafter; they may be transient, disappearing within 48 hours. The petechiae may be the only clinical manifestation of CMV infection. More often, enlargement of the spleen and liver is associated with the finding of petechiae. The petechiae may persist for weeks after birth. Crying, coughing, the application of a tourniquet, performance of a lumbar puncture, or application of restraints of any kind may result in the appearance of petechiae months after birth. Platelet counts in the 1st week of life range from less than 10,000/μL to 125,000/μL, with most in the range of 20,000/μL to 60,000/μL. Some infants with petechial rashes do not have associated thrombocytopenia. Significant bleeding is rarely, if ever, associated with the thrombocytopenia of congenital CMV infection.

#### Microcephaly

Microcephaly, currently defined in epidemiologic studies as a head circumference of less than the third percentile, was found to be present in 14 of 17 patients with CID

**FIGURE 23–4** Symptomatic congenital cytomegalovirus infection manifested by microcephaly and petechiae.

in the early studies of Medearis [504] in 1964. As tissue culture methods became more widely used, and clinical awareness of the infection increased, microcephaly became a less prominent symptom in subsequent series that included mainly infants born with less severe disease. In a more recent examination of 106 surviving patients who were born with symptomatic CMV infection, 53% were microcephalic [385]. Not all infants who are microcephalic in the perinatal period continue to have head circumferences of less than the third percentile later in infancy. Microcephaly is the most specific predictor of future cognitive impairment in congenitally infected infants (this is especially true if the head measurement is close to the fifth percentile in an infant with low birth weight). Intracranial calcifications suggest that the infant will have at least moderate and probably severe delays in cognitive development [398,505].

### Ocular Defects

The principal abnormality related to the eye in CMV infection is chorioretinitis, with strabismus and optic atrophy [207,398,473]. Microphthalmos, cataracts, retinal necrosis and calcification, blindness, anterior chamber and optic disk malformations, and pupillary membrane vestige have also been described in association with generalized congenital CID. Despite the aforementioned, the presence of abnormalities such as microphthalmos and cataracts is strong presumptive evidence that the disease process is not caused by CMV. Chorioretinitis has been reported to occur in approximately 14% of infants born with symptomatic congenital infection [398,473]. Although chorioretinitis occurs less frequently in symptomatic congenital CMV than in congenital toxoplasmosis, lesions caused by CMV and *Toxoplasma* cannot be differentiated on the basis of location or appearance [207,473]. *Toxoplasma gondii* and CMV can induce central retinal lesions. Occasionally, the appearance of strabismus with subsequent referral to an ophthalmologist results in the diagnosis of chorioretinitis. Any infant with suspected CMV infection or strabismus in early life should be examined carefully for retinal lesions. Chorioretinitis caused by CMV differs, however, from that caused by *Toxoplasma* in that postnatal progression is uncommon.

### Fetal Growth Restriction

Intrauterine growth restriction, occasionally severe, was reported in 50% of 106 patients with symptomatic congenital CMV infection, whereas prematurity occurred in 34% (see Table 23–8) [398]. Infants with asymptomatic congenital infection generally do not exhibit intrauterine growth restriction or prematurity, and CMV has not been considered a common cause of either condition in infants without overt clinical findings of congenital CMV infections.

### Pneumonitis

Pneumonitis, a common clinical manifestation of CMV infection after hematopoietic and solid organ transplantation in adults, is not usually a part of the clinical presentation of congenital CMV infection in newborns. Diffuse interstitial pneumonitis occurs in less than 1% of congenitally infected infants, even when the most severely affected cases are considered. CMV-associated pneumonitis has been described in infants with perinatally acquired CMV infections [506].

### Dental Defects

Congenital CMV infection is also associated with a distinct defect of enamel, which so far seems to affect mainly primary dentition [507]. This defect is more severe in children with the symptomatic form of the infection than in children born with asymptomatic infections (Fig. 23–5). The mechanism leading to enamel dysplasia in infants with congenital CMV is unknown.

Clinically, this defect appears on all or nearly all of the teeth and is characterized by generalized yellowish discoloration. The enamel is opaque and moderately soft and tends to chip away from dentin. Affected teeth tend to be susceptible to mechanical trauma leading to dental caries that are frequently seen in these children. In our longitudinal studies, this defect of enamel was documented in 27% of 92 children born with symptomatic congenital CMV infection and in 4% of 267 children who were born with the subclinical form and who were observed for at least 2 years. These patients usually require extensive orthodontic therapy. It is evident that these defects do not involve permanent teeth to the same degree.

### Deafness

Sensorineural deafness is the most common handicap caused by congenital CMV infection. Medearis [504] was the first investigator to call attention to the presence

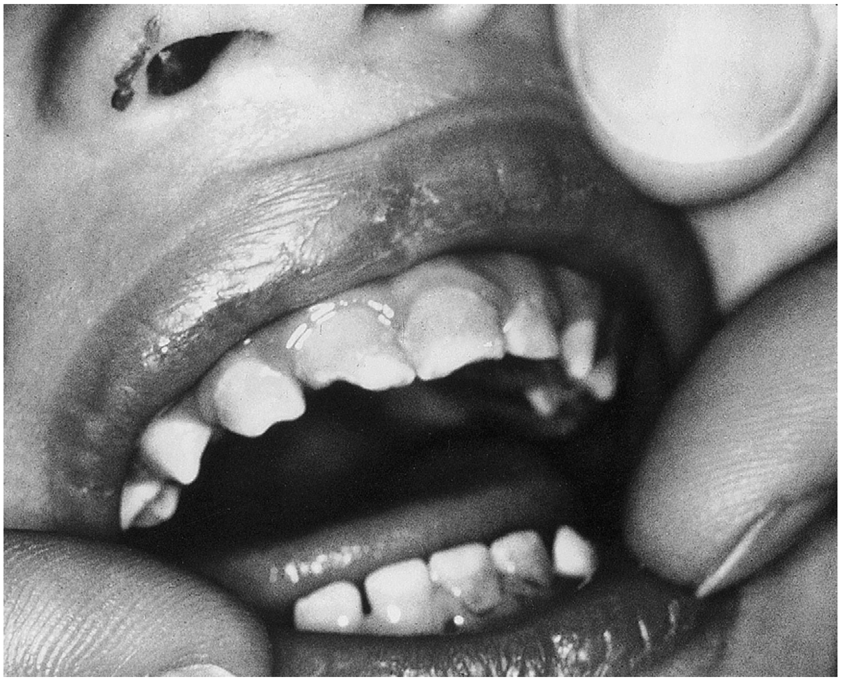

**FIGURE 23–5** **Cytomegalovirus-affected teeth.** This patient had a clinically severe congenital cytomegalovirus infection. Note fractured borders and opaque and hypocalcified enamel.

**TABLE 23–9** Sequelae in Children after Congenital Cytomegalovirus Infection

| Sequelae | % Symptomatic (No.) | % Asymptomatic (No.) |
|---|---|---|
| Sensorineural hearing loss | 58 (58/100) | 7.4 (22/299) |
| Bilateral hearing loss | 37 (37/100) | 2.7 (8/299) |
| Speech threshold moderate to profound (60-90 dB)* | 27 (27/100) | 1.7 (5/299) |
| Chorioretinitis | 20.4 (19/93) | 2.5 (7/281) |
| IQ <70 | 55 (33/60) | 3.7 (6/159) |
| Microcephaly, seizures, or paresis/paralysis | 51.9 (54/104) | 2.7 (9/330) |
| Microcephaly | 37.5 (39/104) | 1.8 (6/330) |
| Seizures | 23.1 (24/104) | 0.9 (3/330) |
| Paresis/paralysis | 12.5 (13/104) | 0 (0/330) |
| Death† | 5.8 (6/104) | 0.3 (1/330) |

of deafness in symptomatic congenitally infected infants. Subsequent reports confirmed this association and provided evidence that CMV can also cause sensorineural hearing loss in children with clinically inapparent congenital infection (Table 23–9).* CMV is now considered one of the most important causes of deafness in childhood and in the United States is thought to be the most common etiology of nonfamilial sensorimotor hearing loss [211,513].

The frequency and severity of hearing impairment are increased in patients with symptomatic infection (58%) compared with asymptomatic infection at birth (7.4%). Generally, hearing loss is progressive in 50% of cases, bilateral in 50%, and of late onset in 20%. The predictors of hearing loss in children with symptomatic congenital CMV infection are intrauterine growth restriction, petechiae, hepatosplenomegaly, thrombocytopenia, and intracerebral calcifications. These are similarly the predictors of significantly higher viral loads in newborn infants [460,461,514,515]. The presence of microcephaly and other neurologic abnormalities in one study failed to predict hearing loss, however [514]. Using logistic regression analysis, only petechiae and intrauterine growth restriction were shown to be independent predictors of hearing loss. As noted previously, the viral load measured in peripheral blood predicts the hearing outcome of infants with congenital infection [460,461,515].

### *Long-Term Outcome*

The likelihood of survival with normal intellect and hearing after symptomatic congenital CMV infection is small [173,385,473,516–521]. As shown in Table 23–9, in our prospective studies, one or more sequelae have occurred in nearly 90% of the patients with symptomatic congenital infection who survived [385].

Psychomotor retardation, usually combined with neurologic complications and microcephaly, occurred in nearly 70% of infants. Sensorineural hearing loss was seen in 50%. The hearing loss is bilateral in 67% of patients with hearing loss and is progressive in 54%. A more recent study from Europe reported a significant incidence of vestibular dysfunction in infants with congenital CMV [522]. Chorioretinitis or optic atrophy occurred in 20%

*References [173,207–209,211,387,398,508–512].

of cases. Expressive language delays independent from hearing loss and mental impairment have also been described. Several studies have searched for clinical predictors of intelligence and developmental outcome and found that microcephaly at birth, development of neurologic abnormalities during the 1st year of life, ocular lesions (chorioretinitis), and microcephaly that became apparent after birth were significantly associated with a low performance on cognitive and developmental testing [476].

A consistent predictor of adverse neurodevelopmental outcome is the presence of cranial computed tomography (CT) abnormalities detected within the 1st month of life [398,505,523]. In infants with symptomatic congenital CMV infection, abnormal CT findings, particularly intracerebral calcifications, are common (70%). Nearly 90% of children with abnormal newborn CT scans develop at least one sequela compared with 29% of children with a normal study [398]. In this particular study, which included 56 children with symptomatic congenital CMV, only 1 child with a normal CT scan had an IQ of less than 70, in contrast to 59% of children with imaging abnormalities. Newborn CT abnormalities were also associated with an abnormal hearing screen at birth and hearing loss on follow-up. None of the neonatal neurologic findings was predictive of an abnormal CT scan [398]. Overall, it can be anticipated that 90% to 95% of infants with symptomatic congenital infections who survive will exhibit mild to severe long-term sequelae.

## Asymptomatic Infection

As indicated in the previous section, nearly 90% of infants with congenital CMV infections have no early clinical manifestations, and their long-term outcome seems to be much better than infants with clinically apparent infections. Nevertheless, there is now solid evidence derived from controlled prospective studies that 10% to 15% of these infants are at risk of developing numerous developmental abnormalities, such as sensorineural hearing loss, microcephaly, motor defects (e.g., spastic diplegia or quadriplegia), mental retardation, chorioretinitis, dental defects, and others that were once thought to be limited to infants with symptomatic congenital infections. These abnormalities usually become apparent within the first 2 years of life [207,210,508,517,524]. Table 23–9 shows results based on a prospective longitudinal study of 330 patients with asymptomatic congenital infection who were followed by using serial clinical, psychometric, audiometric, and visual assessments. Follow-up studies of patients with inapparent congenital CMV infection have also been reported [210,505,521,525–530]. Generally, the findings are consistent with the results of studies from this institution that are presented in Table 23–9.

Most of the patients in these various studies and their controls were from a low socioeconomic background. The most significant abnormality in children born with subclinical congenital CMV infection is hearing loss. Fowler and associates [210] evaluated 307 children with documented asymptomatic congenital CMV infection and compared their audiometric assessments with 76 uninfected siblings of children with asymptomatic congenital CMV infection and 201 children whose neonatal screen for this infection showed negative results. Sensorineural hearing loss occurred only in children with congenital CMV infection. Among them, 22 (7.2%) had hearing loss. The hearing loss was bilateral in 11 of the 22 children (50%). Among the children with hearing loss, further deterioration of hearing occurred in 50% with a median age at first progression of 18 months (range 2 to 70 months). Delayed onset of sensorineural hearing loss occurred in 18% of the children with the median age of detection at 27 months (range 25 to 62 months). Also, fluctuating hearing loss was documented in 22.7% of the children with hearing loss. These results are very similar to results obtained by Williamson and coworkers in Houston [527].

A study in Sweden of more than 10,000 newborns screened for hearing loss and congenital CMV infection found that this congenital infection was the leading cause of sensorineural hearing loss, accounting for 40% of the cases with hearing loss [508]. Hicks and colleagues [513] found 14 cases of congenital CMV infection with sensorineural hearing loss in 12,371 neonates screened for CMV, a rate of approximately 1.1 per 1000 live births. The rate was 0.6 per 1000 when only cases with bilateral loss of 50 dB or greater were considered. These results suggest that CMV infection could account for at least one third of sensorineural hearing loss in young children in the U.S. population [513]. Similar results have been obtained in populations outside of the United States and northern Europe. In a study from Brazil derived from a population of women with greater than 96% seroprevalence for CMV, congenital infection was detected in 1% of newborn infants, and hearing loss (>60 dB) was present in approximately 8% of infected infants [158].

Taken together, these studies indicate that universal screening for hearing loss would detect less than half of all the cases of sensorineural hearing loss caused by congenital CMV infection. Because most of these infants are asymptomatic at birth, they are not recognized as being at high risk for hearing loss and perhaps more importantly are not being tested further to detect late-onset hearing loss. The universal screening of neonates for hearing loss should be combined with screening for congenital CMV infections.

Prospective studies of children with subclinical congenital CMV infections have also revealed a wide but significant spectrum of neurologic complications [527]. It has been estimated that within the first 2 years of life, 2% to 7% of the infants in this group develop microcephaly with various degrees of mental retardation and neuromuscular defects. How often milder forms of brain damage, such as learning or behavioral difficulties, occur as these patients grow older is unknown and not being investigated. Studies of the intellectual development of children with asymptomatic congenital CMV infections have shown conflicting results. One study evaluated 204 prospectively followed children with asymptomatic congenital CMV infections and 177 uninfected siblings ranging in age from 6 to 203 months [531]. Parents were administered a developmental profile, and the children were administered an objective intelligence measure. Results showed that children with asymptomatic congenital

CMV infection did not exhibit intellectual impairment, and they performed similarly to uninfected siblings.

Children with asymptomatic congenital CMV infections have a low risk of chorioretinitis. The current estimate is that it occurs in 2% of these children and, similar to hearing loss, may not be present at birth.

These observations underscore the need for longitudinal follow-up of patients with congenital CMV infection regardless of the initial clinical presentation. Careful assessments of perceptual functions (hearing, visual acuity), psychomotor development, and learning abilities must be made to recognize the full impact of CMV. With early identification of a problem, corrective measures can be instituted to reduce psychosocial and learning problems.

## Effect of Type of Maternal Infection on Symptoms and Long-Term Outcome

Studies have shown that preexisting maternal immunity does not prevent CMV from reactivating during pregnancy and cannot reliably prevent transmission in utero or symptomatic congenital infections.* A prospective study of young, predominantly African American women with one or more previous deliveries was done to estimate the protection conferred by preconception maternal immunity [532]. In the nearly 3500 multiparous women who had previously delivered newborns screened for congenital CMV infection and who subsequently enrolled in this study, the overall rate of congenital CMV infection was 1.3%. Congenital infection occurred in 18 of 604 newborns (3%; 95% confidence interval 1.8% to 4.7%) born to initially seronegative mothers compared with 29 of 2857 newborns (1%; 95% confidence interval 0.7% to 1.4%) born to immune mothers. Of the initially seronegative women, 23.5% seroconverted for an annualized seroconversion rate of 7.8% per year with 12.7% of these seroconversions resulting in congenital CMV infection. Of infants born to mothers immune to CMV before conception, 1% had congenital infection.

These results show that young women who have immunity to CMV from naturally acquired infections have about 60% lower relative risk of delivering an infant with congenital CMV infections within a 3-year period compared with women who were initially seronegative. Although this study confirmed a relative protective effect of preexisting immunity that was first reported nearly 3 decades ago, the absolute protective effect was modest if one considers that nearly twofold more infants with congenital infection were born to women with preexisting serologic immunity than women with primary infection during pregnancy in this same population [532]. This study, together with studies from maternal populations with high seroprevalence for CMV, suggested that although maternal immunity to CMV can limit the incidence of congenital infections presumably by decreasing the rate of transmission, most infants with congenital CMV are born to women with serologic immunity before conception in maternal populations of high CMV seroprevalence.

*References [12,153,154,157,158,160].

It is generally recognized that primary infection has a higher risk of causing symptomatic infection; however, data that have emerged in recent years, including our own prospective studies, raise the possibility that recurrent maternal infection may result in adverse outcome more frequently than previously thought. In 1999, prospective studies done in Sweden and the United States reported the presence of symptoms at birth and the development of long-term sequelae in children born with congenital CMV infection after a recurrence of maternal infection (Table 23–10) [442,533].

Our study included 246 children with congenital CMV infection from the screening of 20,885 neonates (1.18%) [442]. Of the 246 infants, 47 were symptomatic at birth, and 8 of the 47 (17%) were born to mothers with recurrent CMV infection as defined by seropositive status at the time of a previous pregnancy. Demographically, the women in this study have been characterized as predominantly black (93%), single (96%), and young (46% ≤20 years of age), with no private insurance. More recently, a summary of the outcome of congenital CMV infection as a function of the type of maternal infection from a screened population has been tabulated, and from this study it is apparent that damaging congenital infections are frequent after nonprimary maternal infections (Table 23–11) [212].

A more recent study in this population concluded that in women who are seropositive for CMV, reinfection with different strains of CMV rather than reactivation of the endogenous strain can lead to intrauterine transmission and symptomatic congenital infection [160]. In contrast, the study of women who are predominantly white, married, of middle to high socioeconomic background, and older has not revealed the occurrence of symptomatic

* The transmission rate varies depending on the population. Women of lower socioeconomic status have rates reported as high as 2.0%, whereas women from middle and upper middle class socioeconomic groups have rates less than 0.2%.

congenital CMV infection as a result of a recurrence of maternal infection. A summary of available data from nearly 4 decades of study of congenital CMV infections from a single institution has been presented as a schematic of the natural history of congenital CMV infections (Fig. 23–6).

## Public Health Significance

The public health impact of congenital CMV infection in the United States is significant, as shown in Table 23–12. Using models of congenital CMV infection with the average rate of 1% and a birth rate of 4 million per annum, approximately 40,000 infants are born each year with congenital CMV infections. Of these, 2800 infants present with signs and symptoms of infection (CID). About 336 of these infants can be expected to die within the 1st year, and nearly 2160 of the survivors develop handicaps. Another 5580 or so of subclinically infected (asymptomatic infections) infants develop significant hearing and mental deficits. In addition to the personal and family suffering associated with these conditions, the cost to society for caring for these children has been estimated to amount to more than $1 billion each year [534].

**TABLE 23–12** Public Health Impact of Congenital CMV Infection in the United States

| Parameter | Estimated Figure |
|---|---|
| No. live births per year | 4 million |
| Rate of congenital CMV infection (average) | 1% |
| No. infected infants | 40,000 |
| No. infants symptomatic at birth (5%-7%) | 2800 |
| No. with fatal disease (± 12%) | 336 |
| No. with sequelae (90% of survivors) | 2160 |
| No. infants asymptomatic at birth (93%-95%) | 37,200 |
| No. with late sequelae (15%) | 5580 |
| Total no. with sequelae or fatal outcome | 8076 |

## PERINATAL INFECTION

As discussed in previous sections, perinatal infections can be acquired from exposure to virus in the maternal genital tract at delivery, from breast milk, or through multiple blood transfusions [131,453–455,459,535–543]. To establish the diagnosis of perinatal CMV infection, one must first exclude congenital infection by showing an absence of viral excretion during the first 2 weeks of life. Findings suggest that PCR assays can detect viral DNA in saliva or blood specimens from infants exposed to CMV after delivery but not congenitally infected, further indicating that confirmation of congenital CMV infections requires isolation of virus within 2 weeks of birth. The incubation period of perinatal CMV infection is 4 to 12 weeks. Although the quantity of virus excreted by infants with perinatal infection is less than that seen with intrauterine acquisition, the infection is also chronic, with viral excretion persisting for years [544].

Most infants with naturally acquired perinatal infections remain asymptomatic. Most of these infections result from recurrent maternal infections, and infants are born with variable levels of maternal antibody. Asymptomatic perinatal CMV infection in full-term and otherwise healthy infants does not seem to have an adverse effect on growth, perceptual functions, or motor or psychosocial development. CMV has been incriminated as a cause of pneumonitis in infants younger than 4 months [506]. In a study undertaken to define the possible association of CMV and other respiratory pathogens with pneumonitis in young infants, CMV was isolated in 21 of 104 patients (21%) enrolled [506]. Only 3% of 97 hospitalized controls were infected. CMV-associated pneumonitis occurs throughout the year, in contrast with

the common respiratory virus infections, which occur most often in winter and early spring.

In premature and ill full-term infants, Yeager and colleagues [545] originally reported that naturally acquired CMV infection may pose a greater risk. They found that premature infants weighing less than 1500 g at birth who acquired CMV from a maternal source often developed hepatosplenomegaly, neutropenia, lymphocytosis, and thrombocytopenia, coinciding with the onset of virus excretion. Infected newborns required longer treatment with oxygen than uninfected patients. In a later study, Paryani and coworkers [546] from the same group reported a prospective study of 55 premature infants including controls and suggested that there may be a propensity for an increased incidence of neuromuscular impairments, particularly in premature infants with the onset of CMV excretion during the first 2 months of life. Sensorineural hearing loss, chorioretinitis, and microcephaly occurred with similar frequency in both groups. Similar findings were reported by Vochem and colleagues [455] and Maschmann and coworkers [547,646].

In the past, transfusion-acquired perinatal CMV infection was associated with significant morbidity and mortality, particularly in premature infants with a birth weight of less than 1500 g born to CMV-seronegative mothers [174,548]. The syndrome of post-transfusion CMV infection in premature newborns was characterized by Ballard and coworkers [549]. They isolated CMV from 16 of 51 preterm infants of a mean birth weight of 1000 g and found that 14 of the 16 virus-positive infants had a constellation of symptoms that resembled CID. This recognizable, self-limited syndrome consisted of deterioration of respiratory function, hepatosplenomegaly, unusual gray pallor with disturbing septic appearance, an atypical and an absolute lymphocytosis, thrombocytopenia, and hemolytic anemia. The syndrome was more severe in infants with low birth weight and occurred 4 to 12 weeks after the transfusion, when the infants were progressing satisfactorily. Although the course of the disease was generally self-limited (lasting 2 to 3 weeks), death occurred in 20% of the ill infants. Subsequent work by Yeager and associates [545,548] and Adler and colleagues [550] confirmed these observations.

# DIAGNOSIS

## DETECTION OF VIRUS

The diagnosis of congenital CMV infection should be considered in any newborn with signs of congenital infection, if there is a history of maternal seroconversion or a mononucleosis-like illness during pregnancy, or if an infant fails a newborn screening examination. The most reliable method for the diagnosis of congenital infection is virus isolation in tissue culture, which is generally accomplished with urine or saliva or demonstration of CMV DNA by PCR (Table 23–13) [378,551–555].

CMV IgM serology has never been shown to have adequate sensitivity or specificity for the diagnosis of congenital CMV infection. With diagnostic methods that detect the virus, viral antigens, and nucleic acids, it is possible to confirm the diagnosis from blood, cerebrospinal fluid, and biopsy material. Of particular interest is the possibility of diagnosis by PCR on blood stored on filter paper [555,556]. This approach is being studied by many laboratories, and numerous reports have suggested its potential value [515,556–561]. Representative studies include those from Sweden in which CMV DNA was detected in dried blood specimens of 13 of 16 (81%) infants with congenital CMV infection [555]. Italian investigators using a similar method obtained a sensitivity of 100% and a specificity of 98.5% in a study of 205 neonates including 14 with congenital infections [562]. Both groups of investigators used a nested PCR method to detect CMV DNA in dried blood specimens, which added complexity to this assay, reducing its potential use as a screening assay. Large prospective studies have not adequately evaluated the sensitivity and specificity of this approach in screening populations. More recent results from a large ongoing study of greater than 20,000 specimens from screened populations have suggested that dried blood spot testing using PCR is inferior in terms of sensitivity to conventional methodology using inoculation of

**TABLE 23–13** Summary of Available Diagnostic Methods for Identification of Infants with Congenital Cytomegalovirus (CMV) Infection

| Method | Advantages | Disadvantages |
|---|---|---|
| ***Detection of Virus or Viral Antigens*** | | |
| Standard tube culture method | Standard reference method | Takes 2-4 wk, not suitable for screening |
| Shell vial assay | Rapid, sensitive, and commercially available | Expensive, not suitable for screening |
| Microtiter plate immunofluorescent antibody assay | Rapid, sensitive, reliable, simple, inexpensive | Cell culture–based, not commercially available |
| CMV antigenemia | Rapid and simple | Sensitivity and utility for screening newborns unknown, expensive |
| ***Nucleic Acid Amplification Methods*** | | |
| DNA hybridization assay | Sensitive and reliable | Complicated, need for a radiolabeled probe |
| Polymerase chain reaction amplification methods | Simple and can be used to screen large numbers | Utility as a screening assay has not been proved |
| ***Serologic Methods*** | | |
| Anti-CMV IgM antibody assay | Simple and widely available | Low sensitivity and unreliable for screening |

saliva or urine on permissive human fibroblasts followed by detection of immediate early protein by immunologic approaches [563].

To confirm congenital CMV infection, demonstration of virus must be attempted in the first 2 weeks of life because viral excretion after that time may represent an infection acquired at birth (natal) by exposure to an infected birth canal or one acquired in the neonatal period by exposure to breast milk or blood products. In the previous section, it was noted that viral nucleic acid detection by PCR in specimens from saliva or blood within the first 2 weeks of life should be confirmed by detection of viral nucleic acids in urine or virus isolation from urine or both. Although isolation of CMV during the first 2 weeks of life proves a congenital CMV infection, it does not confirm an etiologic relationship with an existing disease. Urine and saliva are the preferred specimens for culture because they contain larger amounts of virus. The viability of CMV is good when specimens are properly stored. When positive urine specimens (without preservatives) are stored at 4° C for 7 days, the rate of isolation decreases to only 93%; it decreases to only 50% after 1 month of storage [564]. Storage and transport at ambient temperature or freezing should never be used because infectivity is rapidly lost.

## TISSUE CULTURE

Standard tissue culture based viral isolation requires inoculation of specimen into monolayers of primary human fibroblasts. Typically, 2 to 4 weeks may be required for the appearance of the characteristic cytopathic effect. Methods for rapid viral diagnosis became available in 1980. Several modifications of the standard tissue culture method combined with immunologic detection of IE CMV-induced antigens have maintained high specificity and sensitivity, yet allowed the confirmation of diagnosis within 24 hours of inoculation of the clinical specimen [565–567].

Typically, this test includes the use of monoclonal antibodies to CMV-specific early antigens with low-speed centrifugation of the clinical specimens onto the monolayer of fibroblasts growing on coverslips inside shell vials [565–567]. When this method was evaluated with clinical specimens (e.g., blood; urine; bronchoscopy lavage; lung, liver, and kidney biopsy samples; sputum), obtained primarily from immunosuppressed patients, the sensitivity approached 80%, and the specificity ranged from 80% to 100%. Subsequently, another adaptation of this rapid immunofluorescent assay used 96-well microtiter plates and a monoclonal antibody that is reactive with the major IE human CMV protein that is expressed in the nucleus of infected cells within hours of virus entry [566]. This rapid assay detected all but 1 of 19 specimens identified by standard virus isolation method from 1676 newborn urine specimens, achieving a sensitivity of 94.5% and a specificity of 100%. This test retained high sensitivity and specificity when saliva instead of urine was tested [568].

To date, the microtiter plate method using either saliva or urine samples is the most rapid, simple to perform, and inexpensive alternative to the standard virus isolation method. It is perfectly suitable for mass screening, and there is no decline in sensitivity for specimens at 4° C for up to 3 days. This study also showed that the sensitivity of the microtiter plate method declined rapidly for specimens from older infants and children with congenital CMV infection and from virus-infected children attending day care centers. It is not recommended for either screening or diagnosing CMV infections in older infants and children.

## DNA HYBRIDIZATION

Rapid diagnosis of CMV has been accomplished by DNA hybridization [569–572]. The sensitivity and specificity of this method is good when the specimens contain 103 or more tissue culture infective doses per milliliter. The methodology is rarely, if ever, used in routine settings, however, and has largely been replaced with PCR-based technologies.

## POLYMERASE CHAIN REACTION AMPLIFICATION

Detection of viral DNA by PCR amplification has proved extremely sensitive and versatile for the detection of CMV genetic material in various clinical samples, including urine, cerebrospinal fluid, blood, plasma, saliva, and biopsy material. In one of the earliest applications of this technology for the diagnosis of congenital CMV, Demmler and associates [553] identified 41 urine specimens positive by PCR from a total of 44 specimens positive by tissue culture. No positive PCR results were found in 27 urine specimens that were negative by tissue culture. In another early study, Warren and coworkers [554] used the PCR technique to detect CMV in saliva from children who were between the ages of 1 month and 14 years and who had either congenital or perinatal CMV infection and compared the results with a standard tissue culture method and microtiter plate detection of immediate early antigen with tissue culture results as a reference. The sensitivity of PCR was 89.2%, and the specificity was 95.8%. Reproducibility was excellent.

If primer selection and amplification conditions are carefully chosen, PCR results are comparable to standard tissue culture isolation of virus except in extreme cases of very low levels of virus infectivity. Some advantages include the minute amount of specimen and the fact that infectious virus is not required, allowing for retrospective diagnosis of CMV infection if the appropriate specimens are available. Nelson and colleagues [551] showed that PCR detection of CMV DNA in serum is a sensitive, specific, and rapid method for diagnosis of infants with symptomatic congenital CMV infection. PCR detected CMV DNA in the serum of 18 infants with symptomatic infection, 1 of 2 infants with asymptomatic infection, and 0 of 32 controls.

Virus isolation from blood specimens is often difficult and insensitive compared with PCR detection of viremia. The use of quantitative PCR (real-time PCR) to detect and quantitate CMV DNA in various clinical specimens, including dried blood spots obtained from a drop of neonatal blood applied to a solid support such as a Guthrie

card at the time of the newborn metabolic screen, could offer diagnostic and prognostic information from a single test. Advantages of PCR-based methods to screen newborn infants include the following: (1) no need for tissue culture facilities; (2) minute amount of specimens; (3) when dried, samples on filter paper are no longer infectious reducing the biohazard risk; (4) easy to ship and transport without occupational exposure to infectious material; (5) possibility to quantify CMV DNA in PCR-positive samples; (6) adaptation of robotic automation; (7) retrospective diagnosis when appropriate specimens are available; and (8) simplified storage at room temperature for many years.

As an example of the value of such an approach that could lead to identification of infants at risk for hearing loss, Boppana and colleagues [460] determined virus burden in the peripheral blood of a group of congenitally infected infants with and without hearing loss. Their findings indicated that it is possible to identify infected infants at higher risk for the development of hearing loss (Fig. 23–7).

## ANTIGENEMIA

An assay to detect CMV antigenemia by means of monoclonal antibodies to the tegument protein pp65 encoded by CMV in polymorphonuclear leukocytes has shown good sensitivity and, perhaps more importantly, good predictive value of the risk of disease compared with conventional methods (serology, culture) for the diagnosis of CMV disease in immunocompromised adults [231, 573–577]. Revello and Gerna [378] assayed pp65 antigenemia, viremia, and DNAemia in peripheral blood leukocytes from 75 infants born to mothers who had primary CMV infection during pregnancy. The results of this study revealed that compared with the technique of virus isolation from urine, the sensitivity of PCR, antigenemia, and viremia were 100%, 42.5%, and 28%. The specificity of the three assays was 100%.

## DETECTION OF IMMUNE RESPONSE

With congenital CMV infection, antibody production begins in utero and is continued probably during the life span of the host.

### Detection of IgG Antibodies

Serologic tests that measure IgG antibody are readily available, easier to perform, and more readily automated than most virologic methods. Their correct interpretation is complicated, however, by the presence of antibodies (IgG class) that are normally transmitted from the mother to the fetus [372]. A negative antibody titer in cord and maternal sera is sufficient evidence in almost all cases to exclude the diagnosis of congenital CMV infection. In uninfected infants born to seropositive mothers, IgG antibodies decrease with a half-life of approximately 1 month and become undetectable by most routine assays by 4 to 9 months of age. In contrast, in infected infants, IgG antibody levels persist for long periods at comparable or sometimes higher levels than in their mothers. CMV infections are commonly acquired during the neonatal period mostly from maternal sources (milk, genital secretions) and blood or blood products, and the distinction from congenital infection is impossible by routine serologic means. In both situations, IgG antibody titers tend to remain stable for many months. A neonatal infection in the face of a negative maternal IgG antibody titer should point to transmission from other sources (e.g., blood transfusion or nosocomial).

Many serologic assays have been described and evaluated for the detection of CMV IgG antibodies. Among these, enzyme-linked immunosorbent assays (ELISAs) are most commonly employed.

### Detection of IgM Antibodies

Infected fetuses usually produce specific IgM antibodies. IgM antibodies are not transferred by the placenta, and their detection in cord or neonatal blood represents a fetal antibody response. There are many different assays for IgM antibodies, but before deciding on the use of any particular test it is important to know its specificity, sensitivity, and reproducibility. No test has so far reached a level of specificity and sensitivity to match the virologic assays described in the previous section.

The solid-phase radioimmunoassay described by Griffiths and Kangro [578] remains among the best, with a reported sensitivity of 89% and a specificity of 100% for diagnosis of congenital CMV infections. With the first generation of commercially available IgM ELISAs, the specificity was nearly 95% with a sensitivity of approximately 70% when evaluating congenitally infected infants [579]. The IgM capture ELISA and other immunoassays have not fared much better when testing for congenital CMV infection. A Western blot format has been used in the study of IgM antibodies in patients with active CMV infection and was based on antibodies reactive with the viral structural polypeptides pp150 and pp52 [580]. Clinicians should not rely on IgM assays to diagnose congenital CMV infection. Continued research in this area may provide a simple and generally available method for

rapid, definitive diagnosis of congenital infections in ill and asymptomatic neonates.

# DIAGNOSIS OF CYTOMEGALOVIRUS INFECTION DURING PREGNANCY

## Clinical Signs and Symptoms

Most primary CMV infections in immunocompetent hosts are subclinical, and infections occurring in pregnant women are no exception. Less than 5% of pregnant women with proven primary CMV infections are symptomatic with an even smaller percentage manifesting mononucleosis-like syndrome. Clinical manifestations have not been reported with recurrent infections (reactivations or reinfections).

## Laboratory Markers

The diagnosis of primary CMV infection can be easily confirmed by documenting seroconversion (i.e., de novo appearance of virus-specific IgG antibodies in a pregnant woman who was seronegative). In the absence of serologic screening, this confirmation is seldom available in clinical practice. The presence of IgG antibodies denotes past infection from 2 weeks to years in duration.

## IgM Assays

Of the several IgM assays commercially available, most perform reasonably well with excellent specificity (95%) and sensitivity (100%) [581–583]. The IgM antibody response varies widely from one patient to another. Seropositivity can be detected for up to 16 weeks, but it is unusual to last more than 1 year. It is typical to see sharp declines in titers within the first 2 to 3 months of infection. More sensitive assays of IgM antibodies have detected maternal CMV specific IgM antibodies 1 year from enrollment in clinical studies [163].

IgM assays have been developed based on recombinant CMV proteins and peptides. Structural and nonstructural CMV-encoded proteins react with IgM antibodies. The detection of specific IgM antibodies can be accomplished by Western blot, immunoblot, or microparticle enzyme immunoassay [580–583]. As noted earlier, sensitivities approaching 98% and specificities of 98% have been claimed with commercially available assays.

## IgG Avidity Assay

The IgG avidity assay is based on the observation that IgG antibodies of low avidity are present during the first months after onset of infection. With time, IgG antibodies of increasingly higher avidity are produced, and eventually only IgG of high avidity is detected in individuals with long-standing CMV infection. An application of this approach was first used to define differences in avidity in women with primary infection who transmitted virus to their offspring [163]. This study showed differences in the avidity of CMV anti-IgG responses that were correlated with the development of virus-neutralizing antibodies, suggesting that maturation of the virus-neutralizing antibody response was linked to avidity maturation of IgG antibody responses [163].

The results of the currently available avidity test are reported as an index representing the percentage of IgG antibody bound to the antigen after denaturation treatment with 6*M* urea [378,552,583–588]. Similar approaches have been reported for other infectious agents, including rubella. In one study, an avidity index value of approximately 20% was obtained in serum samples collected within 3 months after onset of primary infection, in contrast to an avidity index of 78% in sera from individuals with remote infection (Fig. 23–8) [589].

In determining the risk of congenital CMV, a moderate to high avidity index obtained before the 18th week of gestation has a negative predictive value of 100%. When the avidity index is determined at 21 to 23 weeks of gestation, the negative predictive value decreases to 91% [552,590]. The explanation for this observation is that some women who transmitted the infection in utero had acquired the infection at a very early gestational age. One important limitation of early studies using the IgG avidity test was the lack of standardization. In one study, the ability of these IgG avidity assays to identify primary CMV infection almost reached 100%, whereas the ability to exclude a recent infection ranged from 20% to 96%. When coupled with the detection of CMV-specific IgM antibodies, the avidity test has been used to estimate risk

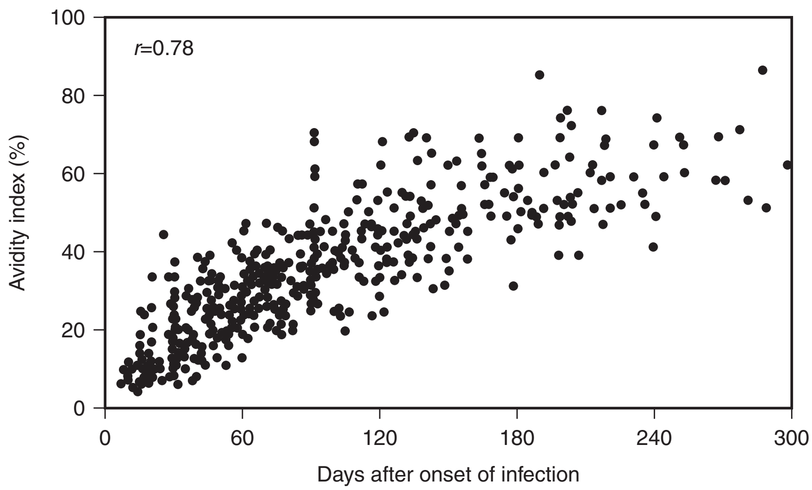

**FIGURE 23–8** Kinetics of IgG avidity index. *(From Revello MG, Gerna G. Diagnosis and management of human cytomegalovirus infection in the mother, fetus, and newborn infant. Clin Microbiol Rev 15:680-715, 2002.)*

of primary infection and damaging congenital infection [552,583,586]. Although this approach has been extensively used in Europe, it is not widely used in the United States presumably because of the lack of widespread screening for CMV infections in pregnant women.

## Viral Cultures

CMV excretion from multiple sites, such as urine, saliva, and genital secretions, is common and can last weeks to several months after a primary infection. The same occurs with reinfections and reactivations, making viral culture as a diagnostic approach of limited value. Viremia, as determined by conventional tissue culture methods, is too insensitive to confirm the diagnosis of primary infection in immunocompetent hosts.

## Other Tests

Other diagnostic methods with greater sensitivity and specificity include the determination of antigenemia (number of pp65-positive peripheral blood leukocytes); PCR quantification of CMV DNA in whole blood (DNAemia), leukocytes (leuko-DNAemia), or plasma; and determination of IE and late messenger RNA (mRNA) in blood (RNAemia). Some of these assays are commercially available. The data supporting their diagnostic value derive largely from studies in immunosuppressed patients with primary CMV infections, reactivations, and dissemination of infection and evaluation of antiviral treatments.

In many cases, individual assays are center specific, and results from one center are often difficult to standardize within other centers. One study of immunocompetent adults including a large proportion of pregnant women with primary CMV infection showed that pp65 antigenemia was detected in 57% of patients examined within the 1st month after the onset of primary infection [591]. The percent of positive results decreased to 25% 1 month later and to 0% 5 months later. Viremia was detected in 26% of patients during the 1st month only. DNAemia (by PCR test) was detected in 100% of patients tested during the first month, in 89% of patients tested during the 2nd month, and in 47% of patients tested 3 months after the onset of primary infection. DNAemia lasted 4 to 6 months in 26% of patients; no patient remained positive beyond 6 months from the onset of infection.

None of the three assays were positive in patients with remote CMV infection, including nine subjects with proven recurrences. The results of this study indicated that antigenemia and DNAemia when run on blood specimens rapidly and specifically diagnosed CMV infection, and it was argued that these assays could provide an estimate of the onset for primary infection in pregnant women [591]. The detection of IE mRNA was also proposed as a diagnostic tool for primary CMV infection in healthy individuals [229,592]. This test was consistently negative in all subjects with old or recurrent CMV infection. In contrast, all subjects within the 1st month of a primary infection tested positive. The proportion of positive results declined over time with all patients testing negative after 6 months of the onset of CMV infection. The kinetics of this test resembled that of DNA detection, and in at least one comparison, the IE mRNA test was slightly more sensitive in the early phase of primary CMV infection [229].

## Maternal Laboratory Tests of Fetal Infection

In utero transmission of CMV infection occurs in approximately 30% to 40% of primary infections acquired during pregnancy [121]. No reliable tests are available so far to identify transmission of infection to the fetus. There are no maternal prognostic markers of fetal infection with recurrent maternal infections. A more recent study has shown that reinfection with a different strain of CMV, as measured by new antibody specificity against epitopes of the virion envelope glycoprotein H, can be associated with symptomatic congenital CMV infection [160]. The methodology used in this study is far from a standard laboratory assay and can identify only maternal reinfections and does not define the risk of a damaging fetal infection.

# PRENATAL DIAGNOSIS

The prenatal diagnosis of CMV is possible by testing fetal blood obtained by cordocentesis and amniotic fluid obtained by amniocentesis. Fetal blood can be used for determination of specific IgM antibodies and direct viral markers. IgM antibodies have been reported to be detectable after 20 weeks of gestation. Because of low sensitivity (approximately 50%), however, it has limited diagnostic value [593–595]. Studies of viral load in fetal blood show that the sensitivity of antigenemia was approximately 58%; of viremia, 55%;, and of DNAemia 82%. The specificity was 100% for the three assays [378]. In one study, PCR in fetal blood had a sensitivity of 41%, whereas viral culture had a sensitivity of only 7%. With the use of fetal blood, even the most sensitive assays miss nearly 15% to 20% of infected fetuses. In addition, the risk of fetal loss after fetal blood sampling must be considered.

Results in amniotic fluid are far better, and this method can be viewed as the current standard for prenatal diagnosis. Viral isolation in tissue culture has a sensitivity of approximately 60%, whereas the sensitivity of PCR can reach 100%. The specificity of both assays is excellent [378,552,593,596,597]. Quantitative PCR has shown that when the amniotic fluid contains $10^5$ or more genome equivalents of CMV DNA, the risk of symptomatic congenital CMV infection is significantly higher than when the viral load is $10^3$ genome equivalents or less [552,598–600].

A confounding factor that remains in prenatal diagnosis of congenital CMV is the gestational age at the time of amniocentesis or cordocentesis. After a primary maternal infection, it may take weeks to months for transplacental transmission of CMV to occur. An interval of 7 weeks between maternal onset of infection and diagnostic tests for fetal infection has been proposed as a reasonable interval by some investigators [596,601–603]. Gestational age at the time of testing is also important because the sensitivity can be only 30% when amniotic fluid is obtained before the 21st week of gestation, whereas it can be 100% if the test is performed after 21 weeks of gestation

[552,594–596,601,602,604–606]. More recently, imaging techniques have been applied to the prenatal diagnosis of congenital CMV infections. The improved specificity for the diagnosis of CNS abnormalities as detected by ultrasound and more recently by magnetic resonance imaging (MRI) suggests that these techniques could contribute significantly to the diagnosis of this intrauterine infection [440,607].

To counsel pregnant women, it is important to remember that most (80% to 90%) children with congenital CMV infection do not have clinically definable CNS sequelae. In the absence of specific antiviral treatment for prenatal therapy, the only options available after a prenatal diagnosis of congenital CMV infection are to terminate the pregnancy and do nothing. The presence or absence of ultrasound evidence of fetal abnormalities should be taken into consideration during counseling of women at risk.

### DIAGNOSIS OF PERINATALLY ACQUIRED INFECTIONS

For perinatally acquired infections, viral culture or CMV DNA detection by PCR from urine and saliva are the preferred diagnostic methods, but CMV excretion usually does not begin until 3 to 12 weeks after exposure. For diagnostic specificity, it is imperative to have a negative result from urine or saliva specimens collected within the first 2 weeks of life. In early infancy, antibody assays have the same limitations described earlier for infants with congenital CMV infection. Differentiation between congenital and perinatal CMV infections is important because the risks of long-term sequelae are very different.

## DIFFERENTIAL DIAGNOSIS

During the newborn period, the constellation of hepatosplenomegaly, petechiae, and direct hyperbilirubinemia with or without pneumonitis, microcephaly, and ocular and neurologic abnormalities that characterizes CID is common to several disease entities, including other congenital infections, such as congenital rubella syndrome, toxoplasmosis, syphilis, neonatal HSV infections, and, less likely, hepatitis B and varicella virus infections. The differential diagnosis of symptomatic congenital CMV infection also includes bacterial sepsis, noninfectious disorders such as hemolytic diseases related to Rh or ABO incompatibilities or red blood cell defects, metabolic disorders such as galactosemia and tyrosinemia, immune thrombocytopenia, histiocytosis X, congenital leukemia, and other diseases in which hepatosplenomegaly is a prominent clinical component. The list of diseases that must be considered in the differential diagnosis becomes broader as the clinical manifestations diminish in severity.

In addition, multiple infections may coexist in the same patient. Consequently, the laboratory work-up for the differential diagnosis must be complete.

### CONGENITAL RUBELLA SYNDROME

Congenital rubella has been virtually eliminated in the United States after the successful immunization program adopted years ago. Although symptomatic congenital rubella and CMV infections share many signs and symptoms, central cataracts, congenital heart defects, raised purpuric rather than petechial rash, salt-and-pepper lesions as opposed to chorioretinitis, and absence of cerebral calcifications are more likely to occur with congenital rubella syndrome than with CID.

### CONGENITAL TOXOPLASMOSIS

Almost all of the manifestations observed in CID have been described for symptomatic congenital toxoplasmosis. Some differences are worth noting. The calcifications of toxoplasmosis are generally scattered throughout the cerebral cortex, whereas the calcifications of CID tend to occur in the periventricular areas. The rash associated with toxoplasmosis is usually maculopapular, but is not petechial or purpuric. Chorioretinitis in the two diseases cannot be differentiated on the basis of appearance or distribution. It is more likely, however, that chorioretinitis related to CMV is associated with other major clinical manifestations, such as microcephaly. The chorioretinitis of toxoplasmosis commonly is an isolated finding.

### CONGENITAL SYPHILIS

The most consistent signs of early congenital syphilis are osteochondritis and epiphysitis on the radiograph of the long bones. These occur in approximately 90% of infected patients and are more likely to appear in patients who become symptomatic in the 1st week of life. Rhinitis, sometimes associated with laryngitis, is another common manifestation of congenital syphilis; it is often followed by a dark red maculopapular rash. Lesions of the skin and mucous membranes are also seen. Hepatosplenomegaly and hepatocellular damage with cholestatic jaundice occur, but are less common in early syphilis than in CID. Calcifications of the brain are not characteristic of congenital syphilis. Choroiditis may be seen.

### NEONATAL HERPES SIMPLEX VIRUS INFECTIONS

Congenital HSV infections are less common than neonatal HSV infections and likely account for approximately 5% of cases of perinatal herpes simplex infections, yet they are more likely to pose a diagnostic dilemma because they may resemble CID. Microcephaly, intracranial calcifications, chorioretinitis with and without optic atrophy, and hepatosplenomegaly are common clinical manifestations of intrauterine HSV infections. The presence of skin vesicles or scarring at birth is valuable for the differential diagnosis. The more common form of HSV infection, neonatal infection, is acquired during parturition and does not usually manifest as an acute disease until 5 to 21 days of age. In contrast to the situation in typical CID, the infant is well during most of the 1st week of life. When illness does occur, it may be accompanied by seizures, encephalitis, respiratory distress, bleeding disorders, and small vesicular lesions that tend to cluster into crops.

# TREATMENT

## CHEMOTHERAPY

A few systemically administered antiviral agents have been used in therapeutic trials of serious, life-threatening or sight-threatening CMV disease. Currently, two antiviral agents, ganciclovir and foscarnet, are licensed for this purpose in immunocompromised patients. Foscarnet inhibits viral replication by inhibiting viral DNA polymerase, and ganciclovir acts as a chain terminator during elongation of the newly synthesized viral DNA.

The Collaborative Antiviral Study Group (CASG) under the auspices of the National Institute of Allergy and Infectious Diseases first conducted a phase II pharmacokinetic and pharmacodynamic study that established the safe dose of ganciclovir to be used in young infants [608]. A phase III randomized, controlled study followed newborn infants with symptomatic congenital infection involving the CNS [609]. The study enrolled 100 patients. Patients in the ganciclovir treatment arm received 6 mg/kg/dose administered intravenously every 12 hours for 6 weeks of treatment. The primary end point was improved hearing (as assessed by brainstem evoked response) between baseline and 6 months of follow-up or, for patients with normal hearing at enrollment, preservation of normal hearing at follow-up. At 6 months, 21 (84%) of 25 ganciclovir-treated patients had hearing improvement or maintained normal hearing compared with 10 of 17 (59%) patients in the no-treatment group ($P = .06$). At 6 months of follow-up, none of the ganciclovir-treated infants had hearing deterioration (0 of 25) compared with 7 of 17 (41%) in the no-treatment group ($P < .01$). Alternatively, 5 of 24 (21%) ganciclovir recipients had worsening in hearing in their best ear between baseline and 1 year or longer compared with 13 of 19 (68%) in the no-treatment group ($P < .01$).

This study was viewed as evidence of the feasibility of treatment of selected cases of congenital CMV infections with an antiviral agent. There were limitations in this study, including a significant number of patients not included in the final analysis and the requirement to treat each ear as a separate data point, a statistically justifiable method, but one that may have uncertain rationale from a standpoint of CNS plasticity and neural development. Regardless of these limitations, the information from this study suggested that at least in some patients, treatment of congenital CMV in the perinatal period could alter the long-term morbidity of this infection.

The most significant toxicity in the treated group was neutropenia with 29 of 46 (63%) patients developing moderate to severe neutropenia compared with 9 of 43 (21%) of the no-treatment group ($P < .01$). Half of the patients with neutropenia required dosage adjustment, and 12% had discontinuation of therapy. This study shows that 6 weeks of intravenous ganciclovir in symptomatic infants with congenital CMV infection prevents worsening of hearing loss at 6 months and 1 year of follow-up. In addition, treated patients had a more rapid resolution of liver function abnormalities and improvements in short-term growth and head circumference compared with controls. There are no reports on the therapeutic efficacy of combined therapy (i.e., foscarnet-ganciclovir). CASG is currently conducting a similar study of valganciclovir, the orally bioavailable prodrug of ganciclovir, to determine if similar results can be obtained using a more convenient alternative to intravenous ganciclovir. So far, anecdotal reports have not supported the use of hyperimmune immunoglobulin or antiviral treatment for the purpose of treating the fetus in utero [360,610].

## PASSIVE IMMUNIZATION

Hyperimmune plasma and immunoglobulin have been used with some success as prophylaxis for primary CMV infections in immunosuppressed transplant patients. A meta-analysis of randomized, controlled trials of immunoglobulin as prophylaxis for CMV disease in adult transplant recipients found a significant beneficial effect [459].

It is unclear if the effect of CMV immunoglobulins on the improved outcome in transplant patients is directly related to their antiviral effects. Some authors have argued that at least in the case of hematopoietic allograft recipients, any benefit from passive transfer of immunoglobulins is secondary to immunomodulatory activities of these biologics.

It has been argued for many years that passive immunoprophylaxis would not work for treatment of congenital infections because the cases are identified weeks and months after infection occurred in utero. An uncontrolled trial performed in Italy in 2005 provided data, however, that raise the possibility that such an approach could limit diseases in the infected fetus and perhaps lessen the risk of transmission from an infected woman.

The study used a commercial source of CMV immunoglobulin to treat women with primary CMV during pregnancy. The passive transfer of antibody reduced the frequency of virus transmission to the offspring and reduced the incidence of disease in infected infants [360]. In addition to being an uncontrolled study, the use of clinical end points that were controversial (i.e., head ultrasound) led to considerable skepticism of the validity of the findings by many investigators. This study raised several provocative questions, however, including the possibility that the beneficial effect of immunoglobulin treatment in this study could be related more to its anti-inflammatory effects on the placenta, rather than a direct antiviral effect within the infected fetus. More questions were generated by this study than addressed; however, this study has increased interest in passive prophylaxis and therapy with biologics as an alternative to vaccines for the prevention of damaging congenital CMV infections.

## VACCINES

In the United States, congenital CMV infection is a significant public health problem. It is the leading cause of sensorineural hearing loss and the leading infectious cause of brain damage in children [611,612]. The Institute of Medicine of the National Academy of Sciences concluded that a vaccine to prevent congenital CMV infection should be a top priority. Despite 30 years of research efforts, no such vaccine is available. The prevailing thought is that neutralizing antibodies and cell-mediated immunity are necessary for prevention. Of the CMV

proteins, gB, gM/gN, pp65, and pp150 can induce neutralizing antibodies and CTL responses [55,613–616]. A major hurdle for the design and testing of vaccines is the lack of a relevant animal model. Each model has drawbacks, perhaps the most significant being that human CMV has unique characteristics in terms of its replication, cellular tropism, and pathogenesis in humans that are not precisely recapitulated in any animal model. Each animal model can study aspects of human CMV infections, but cannot fully reproduce the human disease.

The strategies for vaccine development have included live attenuated vaccine (Towne strain). This vaccine induces a significant antibody response and cell-mediated immunity, as determined by lymphoproliferative response. In CMV-seronegative recipients of kidneys from seropositive donors, this vaccine reduced disease severity, but did not prevent infection [617]. It also protected against a very-low-dose virulent CMV challenge in normal volunteers [618]. In a more recent trial, this vaccine failed to decrease the rate of acquisition of CMV in parents of children in day care centers. The magnitude of the induced immune response was 10-fold lower than that generated by natural infection [619]. The Towne vaccine was not excreted by vaccinees.

### Recombinant Virus Vaccine

The genome of the virulent Toledo strain of CMV, divided into four fragments, was inserted in the genetic background of the attenuated Towne strain gene creating four chimeras. The ability of these four recombinant virus strains to generate antibody and cell-mediated immune responses in the absence of clinical side effects has been evaluated in a phase I study [620].

### Subunit Vaccines

A CMV vaccine based on the envelope glycoprotein gB combined with a novel adjuvant (MF59) was tested in a double-blind, placebo-controlled trial of seronegative adult volunteers [613]. Results showed that after three doses, the antibody responses to gB and neutralizing antibodies exceeded the levels in seropositive control subjects. Cell-mediated immunity as measured by lymphocyte proliferation was generated in vaccinees. A study done in seronegative women suggested that gB subunit vaccine prevented maternal infection as measured by seroconversion in about 50% of vaccinated women, a surprising finding that must be confirmed, but one that does suggest that vaccine immunity against CMV is feasible [621].

A major target of the cell-mediated immune response is pp65. In an effort to elicit this response, a more recent study used the nonreplicating canarypox expression vector in which CMV pp65 has been inserted. A phase I trial on seronegative volunteers found that pp65-specific CTLs were elicited after only two vaccinations. An antibody response to pp65 was also shown. In this preliminary study, the canarypox CMV pp65 recombinant vaccine seems to generate an immune response similar to that provided by natural infection [615]. A canarypox CMV recombinant vaccine that contained gB did not induce neutralizing antibodies. Other approaches have included recombinant alphavirus vectored CMV gB and fusion protein between pp65 and IE-1 [622,623]. This vectored subunit vaccine induced significant neutralizing antibody and interferon-γ responses to T lymphocytes in immunized adult volunteers [624].

Another approach has been the use of the DNA vaccine platform. A clinical trial using a bivalent DNA vaccine (DNA encoding gB and pp65) induced antibodies and cellular immune responses in adult volunteers that included long-term T-lymphocyte memory [625]. Finally, the capacity of CMV to reinfect immune individuals has led several investigators to propose CMV as a vaccine vector for other agents. Findings in rhesus macaques have validated this strategy and have shown not only reinfection of previously immune animals, but also induction of immunity against simian immunodeficiency virus, a model of HIV infection in humans [626]. Together with findings in other animal models of CMV infection and the reported frequency of reinfections in immunocompetent humans, these results suggest that the prevention of infection by this virus is a difficult goal for any vaccine that can induce natural levels of immunity.

## PREVENTION

Generally, CMV is not very contagious, and its horizontal transmission requires close direct contact with infected material—secretions that contain the virus and, less likely, fomites. With the exception of studies that were designed to prevent infection through blood and blood products and grafted organs, no broad-based strategies for preventing the transmission of CMV have been tested. Education of susceptible individuals has been shown to reduce significantly the incidence of infection, a finding that must be incorporated into any vaccine or biologic trial with an end point for preventing maternal infection or limiting congenital infection or both [627].

## PREGNANT WOMEN

An average of 2% of susceptible pregnant women acquire CMV infection during pregnancy in the United States; most of these individuals have no symptoms, and only 40% of the episodes result in fetal infection (see Fig. 23–6) [152,628]. Because there is no proven prenatal therapy, and the risk of fetal morbidity is low, several investigators have concluded that routine serologic screening of pregnant women for primary CMV infections during pregnancy is of limited value. Reliable and inexpensive serologic tests are now available, however, so that women of childbearing age can be informed of their immune status. Because of the risk of congenital infection in offspring of immune women, seroimmune women should also be counseled as to risks of virus exposure and routes of virus acquisition.

Primary CMV infection should be suspected in pregnant women with symptoms compatible with a heterophil-negative, mononucleosis-like syndrome. To define more precisely a recent asymptomatic primary CMV infection, serologic tests such as IgM capture ELISA, IgG avidity index, and DNAemia (PCR) could be used. At present, there are no reliable means to determine whether intrauterine transmission has occurred after symptomatic or subclinical primary infection in early

gestation or to assess the relatively few fetuses at risk for disease. The sensitivity and specificity of prenatal diagnosis by testing fetal blood obtained by cordocentesis or amniotic fluid PCR and viral culture are good after 20 weeks of gestation. There is still limited information to serve as a basis for recommendations regarding termination of pregnancy after a primary CMV infection acquired in early gestation. Similarly, there is no definitive information regarding how long conception should be delayed after documented primary infection is acquired in a woman of childbearing age. Viral excretion is not a sensitive and specific indicator because virus is shed into saliva for weeks or months after infection and into urine and the cervix for months or years.

The data on which to base recommendations for prevention of congenital CMV infection after recurrent maternal infection are even more incomplete. Preexisting immunity does not prevent the virus from reactivating or reinfection, and it does not effectively control the occasional spread to the fetus. Preexisting maternal immunity affords significant protection to the fetus. Evidence that in some high-risk populations reinfections with antigenically different virus can cause fetal disease and long-term sequelae may temper this statement, however. At present, there are no techniques for identifying women with reactivation of CMV that results in intrauterine transmission.

The principal sources of CMV infection among women of childbearing age are exposure to children excreting CMV and sexual contacts. Recommendations for prevention of sexual transmission of CMV are beyond the scope of this chapter. Suffice it to say that they are similar to practices advocated for the prevention of other sexually transmitted infections. As for the risk from exposure to children, susceptible pregnant mothers of CMV-infected children who attend day care centers are at greater risk. Hand washing and simple hygienic measures that are routine for hospital care can be recommended, but it is unrealistic to expect all mothers to comply.

Because CMV has been found to be endemic in the day care setting and is found everywhere in hospitals, questions often arise about the occupational risks to pregnant personnel in these facilities. Although hospital workers do not seem to be at increased risk for CMV infection, personnel who work in day care centers are at increased risk.* In the hospital, universal precautions and routine procedures for hand washing and infection control should make nonparenteral acquisition of CMV infections less likely than in the community. Although most patients who shed CMV are asymptomatic and go unrecognized, when caring for known CMV-excreting patients, these routine measures should be combined with a special recommendation that pregnant caretakers be especially careful in handling such patients [629].

In the day care setting, where hygiene is difficult at best, these preventive measures may be more difficult to implement. Although there is still debate about the need for routine serologic screening of female personnel and day care workers, some investigators believe that it should be recommended for potentially childbearing women whose occupation exposes them to CMV. Knowing their immune status can be helpful in counseling pregnant women at risk. All personnel should be provided with information on prevention measures and reassured that commonsense steps such as hand washing and avoiding contact with secretions should prevent acquisition of infection [627,629]. Attempts to identify all children with congenital CMV infection and children excreting this virus in the workplace so that seronegative workers and parents can avoid contact with them pose serious logistic problems and would require frequent periodic testing.

## NOSOCOMIAL INFECTION

Hospitalized patients who receive blood products and organ transplants are at risk for nosocomial CMV infection. Transfusion of blood products can be an important source of perinatal CMV infections. Early studies showed that the use of blood products from seronegative donors prevents the transmission of CMV and the subsequent risk of disease [175,632–634]. This approach has obvious drawbacks, however, in areas where a large percentage of the donor population is seropositive. The availability of seronegative donors and the additional cost involved in serologic screening and processing the blood must be evaluated by regional blood banks.

Use of filters to remove leukocytes also is an effective means of eliminating post-transfusion CMV infection in adult patients and in newborns, even in low birth weight infants [635–640]. Filtration results in a significant disruption and depletion of leukocytes and is thought to provide a similar reduction in the rate of CMV transmission after transfusion. Studies have shown a 1% to 2% transmission rate of CMV when exclusively CMV-seronegative donor blood has been used, a finding that is in agreement with a more recent finding that 15% of antibody-negative individuals have CMV circulating in peripheral blood mononuclear cells as detected by PCR [113,641]. Many hospitals are using one of these approaches to prevent transfusion-acquired perinatal CMV infections. It is a local hospital and blood bank policy to determine whether transfusion-associated CMV disease is a problem and which method to choose based on their donor populations. Individual nurseries have adopted the policy that all transfusions of blood or blood products should be with seronegative blood, regardless of the infant's birth weight and maternal immune status.

The absence of CMV infection in premature infants born to seronegative mothers and who receive only seronegative blood products suggests that spread of CMV from hands of personnel or from fomites must be rare. Until more information is available, the only logical recommendation is hand washing and routine infection control measures.

Perinatal infection through breast milk is rarely a cause for concern, at least for full-term newborns who receive their mother's milk [454]. Premature infants, who generally do not receive sufficient quantities of specific transplacental antibodies, are at higher risk for morbidity.*

Storage of naturally infected breast milk at −20° C (freezer temperature) significantly reduces, but does not eliminate, infectivity [644,645]. Heat treatment of breast milk at 72° C for 10 seconds eliminates all infectious viruses without affecting the nutritional and immunologic properties of milk [455,537,646].

CHAPTER 24

# Enterovirus and Parechovirus Infections

James D. Cherry • Paul Krogstad

## CHAPTER OUTLINE

Enteroviruses (i.e., coxsackieviruses, echoviruses, newer enteroviruses, and polioviruses) and parechoviruses are responsible for significant and frequent human illnesses, with protean clinical manifestations [1–14]. *Enterovirus* and *Parechovirus* are two genera of the family Picornaviridae [11,13,15,16]. Enteroviruses were first categorized together and named in 1957 by a committee sponsored by the National Foundation for Infantile Paralysis [17]; the human alimentary tract was believed to be the natural habitat of these agents. Enteroviruses and parechoviruses are grouped together because of similarities in physical, biochemical, and molecular properties and shared features in epidemiology and pathogenesis and the many disease syndromes that they cause. Congenital and neonatal infections have been linked with many different enteroviruses and parechoviruses. Representatives of all four major enterovirus groups and parechoviruses have been associated with disease in neonates [1–14,18–35].

Poliomyelitis, the first enterovirus disease to be recognized and the most important one, has had a long history [36]. The earliest record is an Egyptian stele of the 18th dynasty (1580-1350 BC), which shows a young man with a withered, shortened leg, the characteristic deformity of paralytic poliomyelitis [37,38]. Underwood [39], a London pediatrician, published the first medical description in 1789 in his *Treatise on Diseases of Children*. During the 19th century, many reports appeared in Europe and the United States describing small clusters of cases of "infantile paralysis." The authors were greatly puzzled about the nature of the affliction; not until the 1860s and 1870s was the spinal cord firmly established as the seat of the pathologic process. The contagious nature of poliomyelitis was not appreciated until the latter part of the 19th century. Medin, a Swedish pediatrician, was the first to describe the epidemic nature of poliomyelitis (1890), and his pupil Wickman [40] worked out the basic principles of the epidemiology.

The virus was first isolated in monkeys by Landsteiner and Popper in 1908 [41]. The availability of a laboratory animal assay system opened up many avenues of research that in the ensuing 40 years led to the demonstration that an unrecognized intestinal infection was common and that paralytic disease was a relatively uncommon event.

Coxsackieviruses and echoviruses have had a shorter history. Epidemic pleurodynia was first clinically described in northern Germany in 1735 by Hannaeus [3,42] more than 200 years before coxsackievirus as the cause of this disease was discovered. In 1948, Dalldorf and Sickles [43] first reported the isolation of a coxsackievirus by using suckling mouse inoculation.

In 1949, Enders and associates [44] reported the growth of poliovirus type 2 in tissue culture, and their techniques paved the way for the recovery of numerous other cytopathic viruses. Most of these "new" viruses failed to produce illness in laboratory animals. Because the relationships of many of these newly recovered agents

DOI: 10.1016/B978-1-4160-6400-8.00024-9

to human disease were unknown, they were called *orphan viruses* [5]. Later, several agents were grouped together and termed *enteric cytopathogenic human orphan viruses*, or *echoviruses*. Some studies [13–16] of the viral genome of echoviruses 22 and 23 found that they were distinctly different from other enteroviruses, and they have been placed in the new genus, *Parechovirus*.

Live-attenuated oral poliovirus vaccines (OPV) became available in the 1960s, and the most notable advance during recent decades has been the dramatic reduction in worldwide poliomyelitis because of immunization with OPV and efforts of the global immunization initiative [45–50]. The last case of confirmed paralytic polio in the Western Hemisphere, caused by a nonvaccine type, occurred in 1991 [50].

Aside from the polio immunization successes, there have been few major advances or new modes of treatment for enterovirus diseases. The use of nucleic acid detection systems for enterovirus and parechovirus diagnosis has progressed over the past 2 decades, however, and rapid diagnosis of meningitis and other enterovirus and parechovirus illnesses has become possible [19,51–67]. There has been progress in the development of specific anti-enterovirus drugs [68–71].

# VIRUSES

## CLASSIFICATION

Enteroviruses and parechoviruses are RNA viruses belonging to the family Picornaviridae (*pico* means “small”). They are grouped together because they share certain physical, biochemical, and molecular properties. On electron microscopy, the viruses are seen as 30-nm particles that consist of naked (nonenveloped) protein capsids constituting approximately 70% to 75% of the mass of particles and dense central cores (nucleoid) of the genomic RNA [9,11,15,72–86].

The original classification of human enteroviruses is presented in Table 24–1. The enteroviruses were originally distributed into four groups based on their different effects in tissue culture and pattern of disease in experimentally infected animals: polioviruses (causal agents of poliomyelitis in humans and nonhuman primates), coxsackie A viruses (associated with herpangina, human central nervous system [CNS] disease, and flaccid paralysis in suckling mice), coxsackie B viruses (human CNS and cardiac disease, spastic paralysis in mice), and echoviruses (nonpathogenic in mice, not initially linked to human disease).

Although this scheme was initially useful, many strains were subsequently isolated that do not conform to such rigid specificities. Several coxsackievirus A strains replicate and have a cytopathic effect in monkey kidney tissue cultures, and some echovirus strains cause paralysis in mice. For this reason, and to simplify the nomenclature, subsequent enteroviruses were assigned sequential numbers. Following this convention, the prototype enterovirus strains Fermon, Toluca-1, J 670/71, and BrCr (identified 1959-1973) were designated enterovirus 68 through 71. Additional enteroviruses continued to be identified that could not be identified using antisera specific for the classic serotypes. More than 30 additional such enterovirus types have been provisionally assigned, although many have not been linked to human disease.

Complicating matters, studies of echoviruses 22 and 23 found that they exhibited genomic and proteomic differences from other enteroviruses, and they were reclassified in the new genus *Parechovirus* as parechoviruses 1 and 2 [13,15,16]. Similarly, hepatitis A virus was initially assigned the designation of enterovirus 72, but was reclassified as the sole member of the *Hepatovirus* genus within the Picornaviridae family because of marked genetic and biologic distinctions from the enteroviruses.

In recent years, genetic, biologic, and molecular properties have been employed to revise picornavirus taxonomy, leading to a reorganization of human enteroviruses into five groups: the polioviruses and four alphabetically designated human enterovirus species (HEV-A, HEV-B, HEV-C, and HEV-D) (Table 24–2). Determining the nucleotide sequence encoding the viral VP1 capsid protein is important in the approach to taxonomy and predictably identifies viruses originally classified by serologic means, leading to the term *molecular serotyping* [82,84,87,88].

This approach is likely to dominate future phylogenetic studies. Additional reclassification of enteroviruses is likely to occur. It has been proposed that the polioviruses be included as members of the HEV-C species because there does not seem to be any poliovirus-specific nucleotides, amino acid sequence, or motif that allows the three polioviruses to be distinguished from the current HEV-C

**TABLE 24–1** Original Classification of Human Enteroviruses: Animal and Tissue Culture Spectrum*

| | | Cytopathic Effect | | Illness and Pathology | |
|---|---|---|---|---|---|
| **Virus** | **Antigenic Types**† | **Monkey Kidney Tissue Culture** | **Human Tissue Culture** | **Suckling Mouse** | **Monkey** |
| Polioviruses | 1-3 | + | + | – | + |
| Coxsackieviruses A | 1-24‡ | – | – | + | – |
| Coxsackieviruses B | 1-6 | + | + | + | – |
| Echoviruses | 1-34§ | + | ± | – | – |

**Many enterovirus strains have been isolated that do not conform to these categories, leading to the revised classification scheme shown in Table 24–2.*
*†New types, beginning with type 68, were assigned enterovirus type numbers instead of coxsackievirus or echovirus numbers. Types 68-71 were identified.*
*‡Type 23 was found to be the same as echovirus 9.*
*§Echovirus 10 was reclassified as a reovirus, echoviruses 22 and 23 were made the first members of the parechovirus genus of picornaviridae, and echovirus 28 was reclassified as a rhinovirus.*

**TABLE 24–2** Genomic Classification of Enteroviruses

| Species Designation | Original Enterovirus* |
|---|---|
| Poliovirus | Poliovirus types 1-3 |
| Human enterovirus A (HEV-A) | Coxsackievirus A2-8, A10, A12, A14, A16 |
| | Enterovirus 71, 76, 89-92 |
| Human enterovirus B (HEV-B) | Coxsackievirus A9 |
| | Coxsackievirus B1-6 |
| | Echovirus 1-9, 11-21, 24-27, 29-33 |
| | Enterovirus 69, 73-75, 77-78, 93, 97, 98, 100, 101 |
| Human enterovirus C (HEV-C) | Coxsackievirus A1, A11, A13, A17, A19-22, A24 |
| | Enterovirus 95, 96, 99, 102 |
| Human enterovirus D (HEV-D) | Enterovirus 68, 70, 94 |

**Coxsackievirus A15 has been reclassified as a strain of coxsackievirus A11, and coxsackievirus A18 has been reclassified as a strain of coxsackievirus A13.*
*From Fauquet CM, Mayo MA, Maniloff J, Desselberger U, and Ball LA (Eds). Virus Taxonomy. Eighth Report of the International Committee on Taxonomy of Viruses. Elsevier Academic Press, 2005.*

members [89]. The application of molecular phylogenetic approaches has also revealed that recombination between circulating enteroviruses is a frequent event and is likely to increase their genetic diversity [90–98]. This propensity for recombination has played a role in more recent outbreaks of paralytic diseases involving vaccine-derived strains [15].

## MORPHOLOGY AND REPLICATION

The genome of enteroviruses and parechoviruses is a single-stranded, positive-sense RNA molecule approximately 7.4 kilobases in length [83]. It consists of a 5′ noncoding region followed by a single long open-reading frame, a short 3′ noncoding region, and a polyA tail. The 5′ noncoding region contains an internal ribosome entry site, which is essential for the initiation of translation. The 3′ noncoding region folds into highly conserved secondary and tertiary structures that are thought to play a role in the initiation of the replication of the viral genome. This genome is packaged into naked capsids that exhibit icosahedral symmetry with 20 triangular faces and 12 vertices.

Enterovirus replication begins with the adsorption of virions to cell surface receptors, which, for the most part, are integrins or immunoglobulin-like proteins (Table 24–3). The virions penetrate the cell surface, uncoat, and the viral genome functions as messenger RNA for the viral polyprotein. This polypeptide contains three domains, P1 to P3, which are cleaved into three to four proteins each. The P1 region is liberated from the polyprotein by the viral 2A protein, a chymotrypsin-like protease. P1 is initially split into three proteins, VP0, VP1, and VP3, by the viral 3C protease. VP0 is processed further into two smaller proteins, VP4 and VP2. Portions of VP1, VP2, and VP3 are exposed at the surface of the virion, whereas VP4 is entirely internal. VP1, VP2, and VP3 have no sequence homology, but they share the same topology [15]. Specifically, they form an eight-stranded antiparallel β-barrel that is wedge-shaped and composed of two antiparallel β-sheets. The amino acid sequences in the loops that connect the β-strands and the N-terminal and C-terminal sequences that extend from the β-barrel domain of VP1, VP2, and VP3 give each enterovirus its distinct antigenicity.

In contrast to the enteroviruses, the parechovirus 2A protein does not function as a protease. Viral capsids are composed of three proteins: VP2, VP3, and an uncleaved VP0 protein. Although parechoviruses appear structurally similar to other picornaviruses on electron microscopy, the structural arrangement of the three capsid proteins has not been established.

The replication of enteroviruses typically occurs in the cytoplasm in membrane-associated replication complexes and is completed rapidly (5 to 10 hours). Studies of polioviruses and coxsackieviruses have shown that enterovirus replication is associated with disruption of cellular protein secretion, and host-cell protein synthesis is suppressed because of cleavage of eIF4G by the enterovirus 2A protein. The coxsackievirus 2A protein also cleaves dystrophin, a cytoskeletal protein; this activity has been hypothesized to play a role in damage to the myocardium [99,100].

Parechoviruses replicate in a similar fashion [101]. Integrins, $\alpha_v\beta_3$ and perhaps $\alpha_v\beta_1$, are used as receptors, and replication occurs in cytoplasmic structures. As noted previously, the P1 portion of the viral polyprotein is processed into only three capsid proteins, however, and one only protease has been identified in parechoviruses. In addition, parechovirus replication occurs in small, discrete foci in the cytoplasm, rather than in large accumulations

**TABLE 24–3** Cellular Receptors and Cofactors for Infection of Representative Human Enteroviruses (HEV)

| Virus | HEV Species | Receptor | Cofactor for Infection* |
|---|---|---|---|
| Polioviruses 1-3 | Poliovirus | CD155; Pvr (poliovirus receptor) | |
| Coxsackieviruses B1-6 | HEV-B | CAR (coxsackievirus-adenovirus receptor) | CVB 1, 3, 5 may use CD 55 (DAF [decay accelerating factor]) |
| Coxsackievirus A9 | HEV-B | $\alpha_v\beta_3$ integrin (vitronectin receptor) | MAP-70 |
| Echovirus 1, 8 | HEV-B | VLA-2 ($\alpha_2\beta_1$ integrin) | Heparin sulfate |
| Coxsackievirus A13, A17, A20, A21, A24 | HEV-C | ICAM-1 (intercelluar adhesion molecule 1) | |
| Enterovirus 70 | HEV-D | CD55 (DAF) | |

**The cofactors generally facilitate adhesion to cells, but their sole expression is insufficient to permit infection to occur.*

of membranous vesicles as in enteroviruses. Transcription and translation do not seem to be disrupted by parechoviruses, perhaps explaining their relatively mild and delayed cytopathic effect when grown in tissue culture [13].

## REPLICATION CHARACTERISTICS AND HOST SYSTEMS

Enteroviruses and parechoviruses are relatively stable viruses in that they retain activity for several days at room temperature and can be stored indefinitely at ordinary freezer temperatures (−20° C). They are inactivated quickly by heat (>56° C), formaldehyde, chlorination, and ultraviolet light, but are refractory to ether, ethanol, and isopropanol [11,80,102,103].

Enterovirus strains grow rapidly when adapted to susceptible host systems and cause cytopathology in 2 to 7 days. The typical tissue culture cytopathic effect is shown in Figure 24–1; characteristic pathologic findings in mice are shown in Figures 24–2 and 24–3. Final titers of virus recovered in the laboratory vary markedly among different viral strains and the host system used; typically, concentrations of $10^3$ to $10^7$ infectious doses per 0.1 mL of tissue culture fluid or tissue homogenate are obtained. Unadapted viral strains frequently require long periods of incubation. In tissue culture and suckling mice, evidence of growth usually is visible. Blind passage occasionally is necessary for the cytopathology to become apparent.

Although many different primary and secondary tissue culture systems support the growth of various enteroviruses, primary rhesus monkey kidney cultures generally are accepted to have the most inclusive spectrum. Other simian kidney tissue cultures also have the same broad spectrum [104]. Tissue cultures of human origin have a more limited spectrum, but several echovirus types have shown more consistent primary isolation in human than in monkey kidney culture [105–107]. A satisfactory system for the primary recovery of enteroviruses from clinical specimens would include primary rhesus, cynomolgus, or African green monkey kidney; a diploid, human embryonic lung fibroblast cell strain; rhabdomyosarcoma cell line tissue cultures; and intraperitoneal and intracerebral inoculation of suckling mice younger than 24 hours.*

## ANTIGENIC CHARACTERISTICS

Although some minor cross-reactions exist among several coxsackievirus and echovirus types, common group antigens of diagnostic importance have not been defined well. Heat treatment of virions and the use of synthetic peptides have produced antigens with broad enterovirus reactivity [110,111]. These antigens have been used in enzyme-linked immunosorbent assay (ELISA) and complement fixation tests to determine IgG and IgM enterovirus antibodies and for antigen detection. In one study, Terletskaia-Ladwig and colleagues [110] reported the identification of patients infected with enteroviruses by the use of an IgM enzyme immunoassay. This test used heat-treated coxsackievirus B5 and echovirus 9 as antigens, and it identified patients infected with echoviruses 4, 11, and 30. The sensitivity of the test was 35%. In another study involving heat-treated virus and synthetic peptides, the sensitivities were 67% and 62% [111]. Both tests lacked specificity, however. Intratypic strain differences are common findings, and some strains (prime strains) are neutralized poorly by antisera to prototype viruses. In animals, these prime strains induce antibodies that neutralize the specific prototype viruses [9,11,38,77,80].

The identification of poliovirus, coxsackievirus, and echovirus types by neutralization in suckling mice or tissue culture with antiserum pools is relatively well defined.

Neutralization is induced by the epitopes on structural proteins VP1, VP2, and VP3; in particular, several epitopes are clustered on VP1. Prime strains do cause diagnostic difficulty because frequently they are not neutralized by the reference antisera, which is a particular problem with echoviruses 4, 9, and 11 and enterovirus 71. If these types are suspected, this problem can be overcome in some instances by using antisera in less diluted concentrations or antisera prepared against several different strains of problem viruses. Kubo and associates [76] were able to type enterovirus isolates not identified through neutralization by nucleotide sequence analysis of the VP4 gene. They specifically identified prime strains of echovirus 18 and enterovirus 71. Sequence analysis of the VP1 gene also is useful for typing enterovirus prime strains not identified by neutralization [81].

## HOST RANGE

Humans are the only natural hosts of polioviruses, coxsackieviruses, and echoviruses [3–5,12,14,112]. However a total of 18 genetically distinct enteroviruses have been isolated from nonhuman primates [71]. Of 10 of these strains, 7 were related closely genetically to human enteroviruses, whereas the other 3 were related only distantly.

# EPIDEMIOLOGY AND TRANSMISSION

## GENERAL CONSIDERATIONS

Enteroviruses and parechoviruses are spread from person to person by fecal-oral and possibly by oral-oral (respiratory) routes.* Swimming and wading pools may serve as a means of spread of enteroviruses during the summer [114]. Oral-oral transmission via contaminated hands of health care personnel and transmission by fomites have been documented on a long-term care pediatric ward [115]. Echovirus 18 was isolated from human breast milk, and it was possible that enterovirus transmission to the infant occurred through the breast milk [116]. Chang and colleagues [117] detected coxsackievirus B3 in breast milk of two symptomatic mothers, and their infants experienced severe illnesses with hepatic necrosis and meningitis owing to coxsackievirus B3. Enteroviruses have been recovered from trapped flies, and this carriage probably contributes to the spread of human infections, particularly in lower socioeconomic populations that have poor sanitary facilities [118–120].

Children are the main susceptible cohort; they are immunologically susceptible, and their unhygienic habits facilitate spread. Spread is from child to child (by feces to skin to mouth) and then within family groups. Recovery of enteroviruses is inversely related to age; the prevalence of specific antibodies is directly related to age. The incidence of infections and the prevalence of antibodies do not differ between boys and girls.

## TRANSPLACENTAL TRANSMISSION

### Polioviruses

Poliovirus infections in pregnancy can result in abortion, stillbirth, neonatal disease, or no evidence of fetal involvement [121]. Gresser and associates [122] showed that the human amniotic membrane in organ culture can be infected, resulting in a persistent low-grade infection. On many occasions, maternal poliomyelitis occurring late in pregnancy has resulted in transplacental transmission of the virus to the fetus in utero [123–144]. The evidence that transplacental passage of virus occurs in early pregnancy is meager. Schaeffer and colleagues [136] were able to recover virus from the placenta and the fetus after a spontaneous abortion in a 24-year-old woman with poliomyelitis.

Although attenuated poliovirus vaccines have been given to pregnant women, there has never been a search for the transplacental passage of vaccine virus [145–147]. Viremia occurs after oral administration of polio vaccine, and this virus probably is occasionally passed transplacentally to the fetus [148–155].

### Coxsackieviruses

Several investigators have studied coxsackievirus infections in pregnant animals and the transplacental passage of virus to the fetus. Dalldorf and Gifford [156] studied two strains of coxsackievirus B1 and one strain of coxsackievirus A8 in gravid mice. In only one instance (coxsackievirus B1) were they able to recover virus from a fetus. They thought that this result was inconclusive because they were unable to recover virus in five other instances. Berger and Roulet [157] observed muscle lesions in the young of gravid mice infected with coxsackieviruses A1 and B1. Selzer [158] studied several viruses in gravid mice; coxsackievirus A9 was found in the placentas of two mice, but in no fetuses, and coxsackievirus A18 was not recovered from fetuses or placentas. Selzer [158] found that coxsackieviruses B3 and B4 passed the placental barrier. Soike [159] also observed that in the last week of pregnancy, coxsackievirus B3 reached fetal mice transplacentally. Modlin and Crumpacker [160] reported that infection in late gestational mice was more severe than infection occurring in early pregnancy and that transplacental infection of the fetus occurred transiently during the maternal infection. Flamm [161] observed that coxsackievirus A9, when injected intravenously in rabbits, reached the blastocyst early in pregnancy and the amniotic fluid later in pregnancy. He also showed congenital infection in mice with coxsackievirus A1 [162].

Palmer and coworkers [163] studied the gestational outcome in pregnant mice inoculated intravenously with Theiler murine encephalomyelitis virus, a murine enterovirus. In early gestational infections, they found a high rate of placental and fetal abnormalities. The rates of fetal abnormalities and placental infection were greater than the rate of fetal viral infection, suggesting that the adverse effects of the viral infections were direct and indirect. Gestational infection could result in virus passage to the fetus and fetal damage or in placental compromise with indirect fetal damage. In another study using the same murine model with Theiler murine encephalomyelitis virus, Abzug [164] found that maternal factors (i.e., compromised uteroplacental blood flow, concomitant infection, and advanced age) increased the risk of transplacental fetal infection.

In humans, the transplacental passage of coxsackieviruses at term has been documented on several occasions. Benirschke [165] studied the placentas in three cases of congenital coxsackievirus B disease and could find no histologic evidence of infection. In 1956, Kibrick and Benirschke [166] reported the first case of intrauterine infection with coxsackievirus B3. In this instance, the infant was delivered by cesarean section and had clinical evidence of infection several hours after birth. Brightman and colleagues [167] recovered coxsackievirus B5 from the placenta and rectum of a premature infant. No histologic abnormalities of the placenta were identified. Konstantinidou and associates [168] confirmed transplacental infection with coxsackievirus B3 using molecular

*References 1–5,8–10,12,14,112,113.

techniques. At fetal autopsy, they found mild arthrogryposis, necrotic meningoencephalitis with vascular calcifications, interstitial pneumonitis, mild myocardial hypertrophy, and chronic monocytic placental villitis. Coxsackievirus RNA was detected in placental tissue of six infants who had severe respiratory failure and subsequent CNS sequelae [169]. Other evidence of intrauterine infection has been presented for coxsackieviruses A4 and B2 through B6 [170–178].

Evidence for intrauterine infection during the first and second trimesters of pregnancy with coxsackieviruses is less clear. Burch and coworkers [179] reported the results of immunofluorescent studies of two fetuses of 5 months' gestation and one fetus of 6 months' gestation. The 6-month fetus had evidence of coxsackievirus B4 myocarditis; one 5-month fetus showed signs of coxsackievirus B3 infection; and the other 5-month fetus showed evidence of coxsackievirus B2, B3, and B4 infections. Basso and associates [170] recovered coxsackievirus B2 from the placenta, liver, and brain of a fetus after a spontaneous abortion at 3 months' gestation. Plager and coworkers [180] found no evidence of intrauterine viral transmission of coxsackievirus B5 infections during the first and second trimesters of pregnancy.

Euscher and associates [181] detected coxsackievirus RNA in placental tissue from six of seven newborn infants with respiratory difficulties and other manifestations at birth. One of these infants died shortly after birth, and the other six had neurodevelopmental delays. The placentas of 10 normal infants were examined for coxsackievirus RNA, and results of these studies were negative. Three of the placentas from the affected infants showed focal chronic villitis, two showed focal hemorrhagic endovasculitis, and one showed focal calcifications. In addition to respiratory distress, two neonates had rashes, two had seizures, two had thrombocytopenia, and one had intraventricular hemorrhage.

### Echoviruses, Enteroviruses, and Parechoviruses

Less is known about transplacental passage of echoviruses compared with coxsackieviruses and polioviruses. Echovirus infections are regular occurrences in all populations. Women in all stages of pregnancy are frequently infected, and viremia is commonly seen in these infections [182]. In particular, epidemic disease related to echovirus 9 has been studied epidemiologically and serologically [183–185]. In these studies, a search for teratogenesis has been made, but no definitive virologic investigations have been done; asymptomatic transplacental infection might have occurred.

Cherry and colleagues [174] cultured samples from 590 newborns during a period of enterovirus prevalence without isolating an echovirus. Antepartum serologic study of 55 mothers in this study showed that 5 (9%) were actively infected with echovirus 17 during the 6-week period before delivery. In two other large nursery studies, there was no suggestion of intrauterine echovirus infections [186,187].

Berkovich and Smithwick [188] described a newborn without clinical illness who had specific IgM parechovirus 1 antibody in the cord blood, suggesting intrauterine infection with this virus. Hughes and colleagues [189] reported a newborn with echovirus 14 infection who had a markedly elevated level of IgM (190 mg/dL) on the 6th day of life. It seems likely that this infant was also infected in utero. Echoviruses 6, 7, 9, 11, 19, 27, and 33 have been identified in cases of transplacentally acquired infections [143,160–168].

Chow and associates [190] described a 1300-g fetus, which was stillborn after 26 weeks' gestation, with unilateral hydrocephalus, hepatosplenomegaly, fibrotic peritonitis, and meconium staining. Enterovirus 71 was isolated from the amniotic fluid, and the same virus was identified by polymerase chain reaction (PCR) in the cord blood and by immunohistochemical staining in the fetal midbrain and liver. Otonkoski and coworkers [191] reported the occurrence of neonatal type 1 diabetes after possible maternal echovirus 6 infection.

## ASCENDING INFECTION AND CONTACT INFECTION DURING BIRTH

Definitive evidence is lacking for ascending infection or contact infection with enteroviruses during birth. In prospective studies of genital herpes simplex and cytomegalovirus infections, there have been no isolations of enterovirus [192,193]. These results suggest that ascending infections with enteroviruses, if they occur at all, are rare. Reyes and associates [194] recovered coxsackievirus B5 from the cervix of four women in their third trimester, however. Three of the four positive cultures were obtained 3 weeks or more before delivery. In the fourth case, the cervical culture was obtained the day before delivery, and the infant was delivered by cesarean section. All of the infants were healthy, but culture for virus was possible only from the infant delivered by cesarean section; the result was negative. In an earlier study, Reyes and associates [195] reported a child who died of a disseminated echovirus 11 infection. The illness had its onset on the 3rd day of life, and the virus was recovered from the mother's cervix at that time.

Infection with enteroviruses during the birth process seems probable [25,174,196]. The fecal carriage rate of enteroviruses in asymptomatic adults ranges from 0% to 6% or greater in different population groups [197–199]. Cherry and associates [174] found that in 2 (4%) of 55 mothers, enteroviruses were present in the feces shortly after delivery. Katz [200], in a discussion of an infant with neonatal coxsackievirus B4 infection, suggested that the infant might have inhaled maternally excreted organisms during birth. The fact that this infant had pneumonia tends to support the contention. Infections occurring 2 to 7 days after birth could have been acquired during passage through the birth canal.

## NEONATAL INFECTION

Neonatal infections and illnesses from enteroviruses are common [201]. Transmission of enteroviruses to newborns is similar to populations of older people. The main factor in the spread of virus is human-to-human contact.

During the summer and fall of 1981 in Rochester, New York, 666 neonates were cultured for enteroviruses within 24 hours of birth and then weekly for 1 month [195]. The incidence of acquisition of nonpolio enterovirus infections during this period was 12.8%. Two risk factors were identified: lower socioeconomic status and lack of breastfeeding.

## Polioviruses

Clinical poliomyelitis is rare in neonates, but the infection rate before the vaccine era was never determined. It is probable that the rarity of neonatal poliomyelitis was not related to lack of viral transmission, but reflected the protection from disease offered by specific, transplacentally transmitted poliovirus antibodies. From experience gained in vaccine studies, it is apparent that infants with passively acquired antibody can be regularly infected [202–214].

In 1955, Bates [127] reviewed the literature on poliomyelitis in infants younger than 1 month. He described six infants who apparently were not infected by their mothers and who had had other likely contacts. A neighbor was the contact in one case, siblings in two cases, nursery nurses in two cases, and an uncle in the sixth case. In most other infants, the mother had had poliomyelitis shortly before the infant was born and probably was the contact. The mode of transmission—intrauterine, during birth, or postnatal contact—is unknown.

Bergeisen and colleagues [215] reported a case of paralytic poliomyelitis from a type 3 vaccine viral strain. They suggested that the source of this virus might have been the child of the neonate's babysitter, who was vaccinated about 2 weeks before the onset of the illness.

## Coxsackieviruses

Several epidemics with strains of coxsackievirus B in newborn nurseries have been studied. Brightman and coworkers [167] observed an epidemic of coxsackievirus B5 in a premature newborn nursery. Their data suggested that the virus was introduced into the nursery by an infant with a clinically inapparent infection who had been infected in utero. Secondary infections occurred in 12 infants and 2 nurses. The timing of the secondary cases suggested that three generations of infection had occurred and that the nurses had been infected during the second generation. The investigators suggested that the infection had spread from infant to infant and from infant to nurse.

Javett and colleagues [216] documented an acute epidemic of myocarditis associated with coxsackievirus B3 infection in a Johannesburg maternity home. No epidemiologic investigation or search for asymptomatic infected infants was performed. Analysis of the onset dates of the illnesses indicated, however, that single infections occurred for five generations, and then five children became ill within a 3-day period.

Kipps and colleagues [217] performed epidemiologic investigations in two coxsackievirus B3 nursery epidemics. In the first epidemic, the initial infection was probably transmitted from a mother to her child; this infant was the source of five secondary cases in newborns and one illness in a nurse. Infants with four of the five secondary cases were located on one side of the nursery, but only one cot was close to the cot of the index patient, and this cot did not adjoin the cots of the three other infants with contact cases. In the second outbreak, an infant who also was infected by his mother probably introduced the virus into the nursery. Infants with the three secondary cases were geographically far removed from the infant with the primary case of infection.

There have been many other instances of isolated nursery infections and small outbreaks with coxsackieviruses, and it seems that the most consistent source of original nursery infection is transmission from a mother to her child [216–256]. Introduction of virus into the nursery by personnel also occurs, however [232,257].

## Echoviruses and Parechoviruses

Although many outbreaks of echovirus infections have been observed in newborn nurseries, information on viral transmission is incomplete [28,258–286]. Cramblett and coworkers [261] reported an outbreak of echovirus 11 disease in four infants in an intensive care nursery. All infants were in enclosed incubators, and three patients became ill within 24 hours; the fourth child became ill 4 days later. Echovirus 11 was recovered from two members of the nursery staff. These data suggest that transmission from personnel to infants occurred because of inadequate hand washing. In another outbreak in an intensive care unit, the initial patient was transferred to the nursery because of severe echovirus 11 disease [279]. After transfer, infection occurred in the senior house officer and a psychologist in the unit. It was inferred by the investigators that spread by respiratory droplets to nine other infants occurred from these infected personnel.

In a maternity unit outbreak of echovirus 11 involving six secondary cases [275], infection spread through close contact between the infected newborns and the nurses. In another reported nosocomial echovirus 11 outbreak, infants in an intermediate care unit for more than 2 days were more likely to become infected than infants who were there for less than 2 days. Illness was also associated with gavage feeding, mouth care, and being a twin [272].

Modlin [28] reviewed reports of 16 nursery outbreaks involving 206 ill infants. The source was identified in only 4 of the 16 outbreaks, and the primary case in all 4 was an infant who acquired infection vertically from his or her mother. After introduction of an infected newborn into a nursery, spread to other infants by personnel is common [278,282,285,286]. Risk factors for nursery transmission as described by Rabkin and coworkers [282] were "lower gestational age or birth weight; antibiotic or transfusion therapy; nasogastric intubation or feeding; proximity in the nursery to the index patient; and care by the same nurse during the same shift as the index patient."

Wilson and associates [285] reported an intensive care nursery epidemic in which respiratory syncytial virus and echovirus 7 infections occurred concurrently. This epidemic persisted from January to June 1984 despite an aggressive isolation cohorting program. A major factor in persistence was asymptomatic infections with both viruses.

Sato and associates [287] reported a point-source outbreak of echovirus 33 infection in nine newborns related to one nursery over a 10-day period. The primary case was born to a mother who was febrile and who had a high echovirus 33 neutralizing antibody titer in a convalescent-phase serum specimen.

Jack and colleagues [270] observed the endemic occurrence of asymptomatic infection with parechovirus 1 in a nursery during an 8-month period. During this time, 44 infants were infected, and nursery infection occurred when there was no known activity of parechovirus 1 in the community at large. The investigators believed that the endemic viral infection was spread by fecal contamination of hands of nursery personnel. Nakao and colleagues [280] and Berkovich and Pangan [259] also documented parechovirus 1 infections in nurseries. Similar to Jack and colleagues [270], they observed that the infections seemed to be endemic to the nurseries, rather than related to community epidemics.

## HOST RANGE

It is the general opinion that humans are the only natural hosts of enteroviruses [112]. Enteroviruses have been recovered, however, in nature from sewage [119], flies [118–120], swine [288,289], dogs [290,291], a calf [292], a budgerigar [293], a fox [294], mussels [295], and oysters [296]. Serologic evidence of infection with enteroviruses similar to human strains has been found in chimpanzees [297], cattle [298], rabbits [299], a fox [300], a chipmunk [301], and a marmot [262]. It is probable that infection of these animals was the result of their direct contact with an infected human or infected human excreta. Although enteroviruses do not multiply in flies, flies seem to be a possible significant vector in situations of poor sanitation and heavy human infection. The contamination of shellfish is also intriguing [294,295,299–304] because in addition to their possible role in human infection, they offer a source of enterovirus storage during cold weather. Contaminated foods are another possible source of human infection [305].

## GEOGRAPHIC DISTRIBUTION AND SEASON

Enteroviruses and parechoviruses have a worldwide distribution [2,9,112,305,306]. Neutralizing antibodies for specific viral types have been found in serologic surveys throughout the world, and most strains have been recovered in worldwide isolation studies. In any one area, there are frequent fluctuations in predominant types. Epidemics probably depend on new susceptible persons in the population rather than on reinfections; they may be localized and sporadic and may vary in cause from place to place in the same year. Pandemic waves of infection also occur.

In temperate climates, enterovirus infections occur primarily in the summer and fall, but in the tropics, they are prevalent all year [9,112,307]. A basic concept in understanding their epidemiology is the far greater frequency of unrecognized infection than that of clinical disease. This concept is illustrated by poliomyelitis, which remained an epidemiologic mystery until it was appreciated that unrecognized infections were the main source of contagion. Serologic surveys were instrumental in elucidating the problem. In populations living in conditions of poor sanitation and hygiene, epidemics do not occur; but wide dissemination of polioviruses has been confirmed by showing the presence of specific antibodies to all three types in nearly 100% of children by age 5 years.

Epidemics of poliomyelitis first began to appear in Europe and the United States during the latter part of the 19th century; they continued with increasing frequency in economically advanced countries until the introduction of effective vaccines in the 1950s and 1960s [36,37,307,308]. The evolution from endemic to epidemic follows a characteristic pattern, beginning with collections of a few cases, then endemic rates that are higher than usual, followed by severe epidemics with high attack rates.

The age group attacked in endemic areas and in early epidemics is the youngest one; more than 90% of paralytic cases begin in children younger than 5 years. After a pattern of epidemicity begins, it is irreversible unless preventive vaccination is carried out. Because epidemics recur over years, there is a shift in age incidence such that relatively fewer cases are in the youngest children; the peak often occurs in the 5- to 14-year-old group, and an increasing proportion is in young adults. These changes are correlated with socioeconomic factors and improved standards of hygiene; when children are protected from immunizing infections in the first few years of life, the pool of susceptible persons builds up, and introduction of a virulent strain often is followed by an epidemic [309].

Extensive use of vaccines in the past 5 decades has resulted in elimination of paralytic poliomyelitis from large geographic areas, but the disease remains endemic in various parts of the world. Although seasonal periodicity is distinct in temperate climates, some viral activity does occur during the winter [310]. Infection and acquisition of postinfection immunity occur with greater intensity and at earlier ages among crowded, economically deprived populations with less efficient sanitation facilities.

Molecular techniques have allowed the study of genotypes of specific viral types in populations over time [310–313]. Mulders and colleagues [314] studied the molecular epidemiology of wild poliovirus type 1 in Europe, the Middle East, and the Indian subcontinent. They found four major genotypes circulating. Two genotypes were found predominantly in Eastern Europe, a third genotype was circulating mainly in Egypt, and the fourth genotype was widely dispersed. All four genotypes were found in Pakistan.

The epidemiologic behavior of coxsackieviruses and echoviruses parallels that of polioviruses; unrecognized infections far outnumber infections with distinctive symptoms. The agents are disseminated widely throughout the world, and outbreaks related to one or another type of virus occur regularly. These outbreaks tend to be localized, with different agents being prevalent in different years. In the late 1950s, echovirus 9 had a far wider circulation, however, sweeping through a large part of the world and infecting children and young adults. This

behavior has been repeated occasionally with other enteroviruses; after a long absence, a particular agent returns and circulates among susceptible persons of different ages who have been born since the previous epidemic occurred. Other agents remain endemic in a given area, surfacing as sporadic cases and occasionally as small outbreaks. Multiple types are frequently active at the same time, although one agent commonly predominates in a given locality.

There are no available data on the incidence of symptomatic congenital and neonatal enterovirus infections. From the frequency of reports in the literature, it seems that severe neonatal disease caused by enteroviruses decreased slightly during the late 1960s and early 1970s and then became more common again. In 2007, there was an increase in the detection of severe neonatal disease owing to coxsackievirus B1 infection [315].

The five most prevalent nonpolio enterovirus isolations per year in the United States from 1961–2005 are shown in Table 24–4 [6,316–323]. Most patients from whom viruses were isolated had neurologic illnesses. It is possible that other enteroviruses were also prevalent, but did not produce clinical disease severe enough to cause physicians to submit specimens for study. Many coxsackievirus A infections, even in epidemic situations, probably went undiagnosed because suckling mouse inoculation was not performed. Although more than 62 nonpolio enterovirus types and 6 parechovirus types have been identified, only 24 different virus types have been noted in the 45 years covered in Table 24–4.

Khetsuriani and associates [33] at the Centers for Disease Control and Prevention (CDC) presented an extensive report on enterovirus surveillance in the United States for the period 1970-2005. During this period, the five most common enterovirus isolates in order have been echovirus 9, echovirus 11, echovirus 30, coxsackievirus B5, and echovirus 6. During the most recent period (2000-2005), the most common isolates in order have been echovirus 9, echovirus 30, echovirus 18, echovirus 13 and coxsackievirus B5. Similar data are available for the most common enterovirus isolates in Spain from 1988-1997 and Belgium from 1980-1994 [324,325]. The most common enterovirus isolated in both countries was echovirus 30. In 1997 and 1998, major epidemic disease caused by enterovirus 71 occurred in Taiwan, Malaysia, Australia, and Japan [325–329].

An analysis of the CDC nonpolio enterovirus data for 14 years found that early isolates in a particular year were predictive of isolates for the remainder of that year [323]. The six most common isolates during March, April, and May were predictive of 59% of the total isolates during July through December of the same year.

Although the use of live poliovirus vaccine has eliminated epidemic poliomyelitis in the United States, it is hard to determine what effect poliovirus vaccine has had on enterovirus ecology. In 1970, polioviruses accounted for only 6% of the total enterovirus isolations from patients with neurologic illnesses [330]. Although the figures are not directly comparable, more than one third of the enterovirus isolations in 1962 from similar patients were polioviruses [331]. Horstmann and associates [332] studied specimens from sewage and asymptomatic children during the vaccine era and found that the number of yearly poliovirus isolations (presumably vaccine strains) was greater than the number of nonpolio enteroviruses. The prevalence of vaccine viruses did not seem to affect the seasonal epidemiology of other enteroviruses.

# PATHOGENESIS

## EVENTS DURING PATHOGENESIS

Congenital infections with enteroviruses result from transplacental passage of virus to fetus. The method of transport from mother to fetus is poorly understood. Maternal viremia during enterovirus infections is common, and because virus has been recovered from the placenta on several occasions, it is probable that active infection of the placenta also occurs. Benirschke [165] found no histologic evidence of placental disease in three cases of established transplacentally acquired coxsackievirus B infections. Batcup and associates [333] found diffuse perivillous fibrin deposition with villous necrosis and inflammatory cell infiltration of the placenta in a woman who 2 weeks previously, at 33 weeks' gestation, had coxsackievirus A9 meningitis. The woman was delivered of a macerated, stillborn infant. At birth, virus was recovered from the placenta, but not from the stillborn infant.

It is assumed that infection in the fetus results from hematogenous dissemination initiated in the involved placenta. It is also possible that some in utero infection results from the ingestion of virus contained in amniotic fluid; in this situation, primary fetal infection involves the pharynx and lower alimentary tract. The portal of entry of infection during the birth process and the neonatal period is similar to that for older children and adults.

Figure 24–4 shows a schematic diagram of the events of pathogenesis. After initial acquisition of virus by the oral or respiratory route, implantation occurs in the pharynx and the lower alimentary tract. Within 1 day, the infection extends to the regional lymph nodes. On about the 3rd day, minor viremia occurs, resulting in involvement of many secondary infection sites. In congenital infections, infection is initiated during the minor viremia phase. Multiplication of virus in secondary sites coincides with the onset of clinical symptoms. Illness can vary from minor to fatal infections. Major viremia occurs during the period of multiplication of virus in the secondary infection sites; this period usually lasts from the 3rd to the 7th days of infection. In many echovirus and coxsackievirus infections, CNS involvement apparently occurs at the same time as other secondary organ involvement. This occasionally seems to happen with poliovirus infections; however, more commonly, the CNS symptoms of poliomyelitis are delayed, suggesting that seeding occurred later in association with the major viremia.

Cessation of viremia correlates with the appearance of serum antibody. The viral concentration in secondary infection sites begins to diminish on about the 7th day. Infection continues in the lower intestinal tract for prolonged periods, however.

**TABLE 24–4** Predominant Types of Nonpolio Enterovirus Isolations in the United States: 1961-2005*

| | Five Most Common Viral Types per Year | | | | |
|---|---|---|---|---|---|
| **Year** | **First** | **Second** | **Third** | **Fourth** | **Fifth** |
| 1961 | Coxsackievirus B5 | Coxsackievirus B2 | Coxsackievirus B4 | Echovirus 11 | Echovirus 9 |
| 1962 | Coxsackievirus B3 | Echovirus 9 | Coxsackievirus B2 | Echovirus 4 | Coxsackievirus B5 |
| 1963 | Coxsackievirus B1 | Coxsackievirus A9 | Echovirus 9 | Echovirus 4 | Coxsackievirus B4 |
| 1964 | Coxsackievirus B4 | Coxsackievirus B2 | Coxsackievirus A9 | Echovirus 4 | Echovirus 6, coxsackievirus B1 |
| 1965 | Echovirus 9 | Echovirus 6 | Coxsackievirus B2 | Coxsackievirus B5 | Coxsackievirus B4 |
| 1966 | Echovirus 9 | Coxsackievirus B2 | Echovirus 6 | Coxsackievirus B5 | Coxsackievirus A9, A16 |
| 1967 | Coxsackievirus B5 | Echovirus 9 | Coxsackievirus A9 | Echovirus 6 | Coxsackievirus B2 |
| 1968 | Echovirus 9 | Echovirus 30 | Coxsackievirus A16 | Coxsackievirus B3 | Coxsackievirus B4 |
| 1969 | Echovirus 30 | Echovirus 9 | Echovirus 18 | Echovirus 6 | Coxsackievirus B4 |
| 1970 | Echovirus 3 | Echovirus 9 | Echovirus 6 | Echovirus 4 | Coxsackievirus B4 |

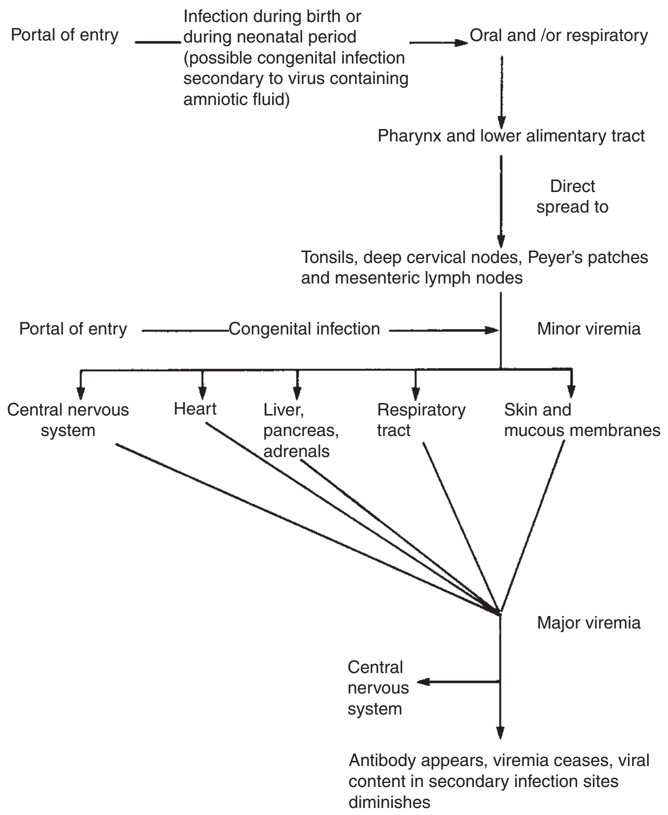

**FIGURE 24–4** Pathogenesis of congenital and neonatal enterovirus infections.

## FACTORS THAT AFFECT PATHOGENESIS

The pathogenesis and pathology of enterovirus and parechovirus infections depend on the virulence, tropism, and inoculum concentration of virus and on many specific host factors. Enteroviruses have marked differences in tropism and virulence. Although some generalizations can be made in regard to tropism, there are marked differences even among strains of specific viral types. Differences in virulence of specific enterovirus types may be the result of recombination among enteroviruses or point mutations [333–335].

Enterovirus infections of the fetus and neonate are thought to be more severe than similar infections in older individuals. This is undoubtedly true for coxsackievirus B infections and probably for coxsackievirus A, echovirus, and poliovirus infections as well. Although the reasons for this increased severity are largely unknown, several aspects of neonatal immune mechanisms offer clues. The similarity of coxsackievirus B infections in suckling mice to infections in human neonates has provided a useful animal model. Heineberg and coworkers [336] compared coxsackievirus B1 infections in 24-hour-old suckling mice with similar infections in older mice. They observed that adult mice produced interferon in all infected tissues, whereas only small amounts of interferon were identified in the liver in suckling mice. The investigators thought that the difference in outcome of coxsackievirus B1 infections in suckling and older mice could be explained by the inability of the cells of the immature animal to elaborate interferon. Additional studies of abnormalities of innate immunity in neonates may enhance our understanding of the severity of enterovirus infections in newborns [337].

Other investigators thought that the increased susceptibility of suckling mice to severe coxsackievirus infections was related to the transplacentally acquired, increased concentrations of adrenocortical hormones [338,339]. Kunin [340] suggested that the difference in age-specific susceptibility might be explained at the cellular level. He showed that various tissues of newborn mice bound coxsackievirus B3, whereas tissues of adult mice were virtually inactive in this regard [340,341]. It has been suggested that the progressive loss of receptor-containing cells or of receptor sites on persisting cells with increasing age might be the mechanism that accounts for infections of lesser severity in older animals. Supporting this suggestion, Ito and colleagues [342] showed that coxsackievirus-adenovirus receptor expression decreases with increasing age in rats. Teisner and Haahr [343] suggested that the increased susceptibility of suckling mice to severe and fatal coxsackievirus infections might be from physiologic hypothermia and poikilothermia during the 1st week of life.

In the past, it was assumed that specific pathology in various organs and tissues in enterovirus infections was caused by the direct cytopathic effect and tropism of a particular virus. Numerous studies using murine myocarditis model systems have suggested, however, that host immune responses contribute to the pathology [13,307,316–331]. These studies suggest that T cell–mediated processes and virus-induced autoimmunity cause acute and chronic tissue damage. Other studies suggest that the primary viral cytopathic effect is responsible for tissue damage and that various T-cell responses are a response to the damage, not the cause [344].

From our review of various murine myocarditis model systems, it is apparent that the genetics of the hosts and of the viral strains determine the likelihood of autoimmune, cell-mediated cellular damage [333,343,345–354]. None of the model systems is appropriate, however, for the evaluation of the pathogenesis of neonatal myocarditis. Although available studies suggest that enterovirus-induced myocarditis in older children and adults occasionally may have a delayed cell-mediated component, the short incubation period and fulminant nature of neonatal disease and the similar infection in suckling mice suggest that autoimmune factors are not of major importance in the pathogenesis of myocarditis in neonates.

During the last 45 years, the clinical manifestations caused by several enterovirus serotypes have changed. Echovirus 11 infection initially was noted in association with an outbreak of upper respiratory infection in a day-nursery more than 50 years ago [355]. In the 1960s, it was found to be related to exanthem and aseptic meningitis [221,356]. Following this and occurring presently is the association of echovirus infection and severe sepsis-like illnesses with hepatitis in neonates.*

*References 195,262,277,279,282,284,357–364.

Another example relates to enterovirus 71 infections. Initially, this virus was noted in association with aseptic meningitis with only a few cases also having exanthem [365,366]. During the last decade, severe epidemic disease with enterovirus 71 occurred in Taiwan, Singapore, Australia, Malaysia, and Japan. In these epidemics, hand-foot-and-mouth syndrome was a major finding, and neurologic disease was more severe than in the past [367–374].

These phenotypic changes could be the result of point mutations or the result of recombination among enteroviruses.* Chan and AbuBakar [91] presented evidence indicating that a recombination event occurred between enterovirus 71 and coxsackievirus A16.

# PATHOLOGY

## GENERAL CONSIDERATIONS

Great variations in the clinical signs of congenital and neonatal enterovirus infections are paralleled by wide variations in pathology. Because pathologic material usually is available only from patients with fatal illnesses, the discussion in this section considers only the more severe enterovirus manifestations. These fatal infections account for only a small portion of all congenital and neonatal enterovirus infections, however. The pathologic findings in infants with milder infections, such as nonspecific febrile illness, have not been described.

## POLIOVIRUSES

The pathologic findings in fatal neonatal poliomyelitis are similar to findings in disease of older children and adults [29,123,126,130,141]. The major findings have involved the CNS, specifically the anterior horns of the spinal cord and the motor nuclei of the cranial nerves. Involvement is usually irregularly distributed and asymmetric. Microscopically, the anterior horn cells show neuronal destruction, gliosis, and perivascular small round cell infiltration. Myocarditis has also been observed [126], characterized by focal necrosis of muscle fibers and various degrees of cellular infiltration.

## COXSACKIEVIRUS A STRAINS

Records of neonatal illnesses associated with coxsackievirus A strains are rare [378–380]. In a study of sudden unexpected death in infants, Gold and coworkers [380], recovered coxsackievirus A4 from the brains of three children. Histologic abnormalities were not identified in the brains or spinal cords of these patients. Baker and Phillips [378] reported the death of twins in association with coxsackievirus A3 intrauterine infections; the first twin was stillborn, and the second twin died when 2 days old of viral pneumonia. Eisenhut and associates [381] described a full-term neonate with coxsackievirus A9 infection with meningitis, myocarditis, and disseminated intravascular coagulation who died on the 7th day of life.

## COXSACKIEVIRUS B STRAINS

Of the enteroviruses, coxsackievirus B strains have been most frequently associated with severe and catastrophic neonatal disease. The most common findings in these cases have been myocarditis or meningoencephalitis or both. Involvement of the adrenals, pancreas, liver, and lungs has occurred.

### Heart

Grossly, the heart is usually enlarged, with dilation of the chambers and flabby musculature [166,177,216,226,229]. Microscopically, the pericardium frequently contains some inflammatory cells, and thickening, edema, and focal infiltrations of inflammatory cells may be found in the endocardium. The myocardium (Fig. 24–5) is congested and contains infiltrations of inflammatory cells (i.e., lymphocytes, mononuclear cells, reticulum cells, histiocytes, plasma cells, and polymorphonuclear and eosinophil leukocytes). Involvement of the myocardium is often patchy and focal, but occasionally is diffuse. The muscle shows loss of striation, edema, and eosinophilic degeneration. Muscle necrosis without extensive cellular infiltration is common.

**FIGURE 24–5 Coxsackievirus B4 myocarditis in a 9-day-old infant.** Notice myocardial necrosis and mononuclear cellular infiltration.

*References 91,92,94,95,97,375–377.

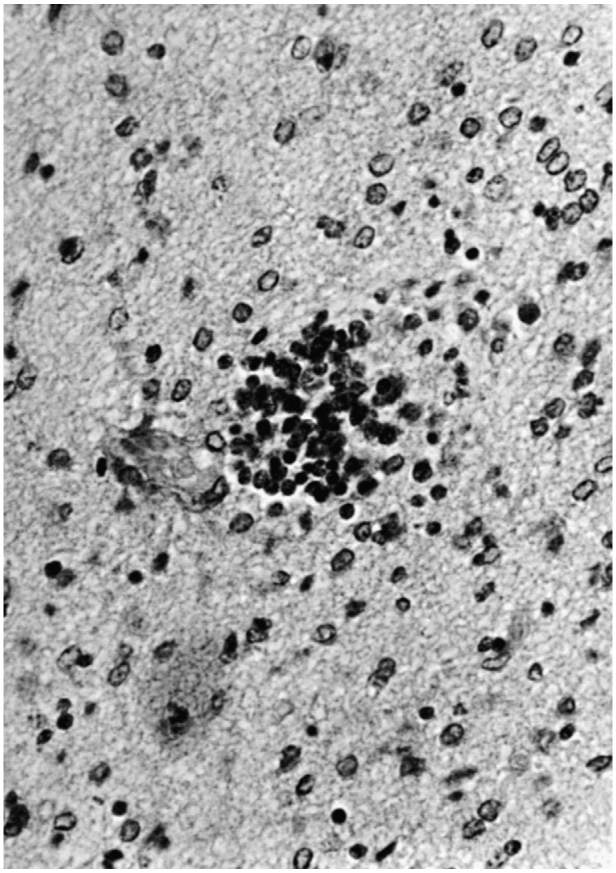

**FIGURE 24–6 Coxsackievirus B4 encephalitis in a 9-day-old infant.** Notice focal infiltrate of mononuclear and glial cells.

## Brain and Spinal Cord

The meninges are congested, edematous, and occasionally mildly infiltrated with inflammatory cells.* Lesions in the brain and spinal cord are focal rather than diffuse, but frequently involve many different areas. The lesions consist of areas of eosinophilic degeneration of cortical cells, clusters of mononuclear and glial cells (Fig. 24–6), and perivascular cuffing. Occasionally, areas of liquefaction necrosis unassociated with inflammation are seen.

## Other Organs

The lungs commonly have areas of mild focal pneumonitis with peribronchiolar mononuclear cellular infiltrations [166,200,229,242]. Massive pulmonary hemorrhage has been observed. The liver is frequently engorged and occasionally contains isolated foci of liver cell necrosis and mononuclear cell infiltrations. A neonate with a coxsackievirus B1 infection developed a sepsis-like illness on the 4th day of life with severe hepatitis and subsequently developed progressive liver calcifications [382]. In the pancreas, infiltration of mononuclear cells, lymphocytes, and plasma cells has been observed, and occasional focal degeneration of the islet cells occurs. Congestion has been observed in the adrenal glands, with mild to severe cortical necrosis and infiltration of inflammatory cells.

*References 166,177,200,226,229,242.

# ECHOVIRUSES

In an earlier period, although frequently responsible for neonatal illnesses, echoviruses were rarely associated with fatal infections. During the past 30 years, however, there have been many reports of fatal illnesses in newborns from echovirus type 11.* In virtually all cases, the major pathologic finding was massive hepatic necrosis; other findings included hemorrhagic necrosis of the adrenal glands, hemorrhage in other organs, myocardial necrosis, and acute tubular necrosis of the kidneys. Wang and colleagues [364] studied four neonates (three with echovirus 11 infections and one with echovirus 5 infection) with fulminant hepatic failure and observed two histopathologic patterns associated with minimal inflammation, but extensive hemorrhagic necrosis. One pattern showed ongoing endothelial injury with endotheliitis and fibrinoid necrosis. The second pattern, which was seen in the two neonates who initially survived, showed veno-occlusive disease.

Virus has not been identified in hepatocytes. Extensive myositis of the strap muscles of the neck occurred in one case [360]. Massive hepatic necrosis has also occurred in infections with echoviruses 3, 5, 6, 7, 9, 14, 19, 20, and 21.† Wreghitt and associates [389] described a neonate with a fatal echovirus 7 infection. This infant was found to have massive disseminated intravascular coagulation, with bleeding in the adrenal glands, renal medulla, liver, and cerebellum.

At autopsy, one infant with echovirus 6 infection was found to have cloudy and thickened leptomeninges, liver necrosis, adrenal and renal hemorrhage, and mild interstitial pneumonitis [363]. One infant with echovirus 9 infection had an enlarged and congested liver with marked central necrosis [387], and another with this virus had interstitial pneumonitis without liver involvement [390]. Three infants with echovirus 11 infections had renal and adrenal hemorrhage and small-vessel thrombi in the renal medulla and in the medulla and the inner cortex of the adrenal glands [279]. In these patients, the livers were normal. Two infants, one with echovirus 6 and the other with echovirus 31 infection, had only extensive pneumonias [274,391]. Willems and colleagues [392] described an infant with echovirus 11 infection who had pneumonia, persistent pulmonary hypertension and purpura fulminans.

# CLINICAL MANIFESTATIONS

In this section we present clinical manifestations by the specific viral agents and by serotypes of the specific viruses. Many infections with enteroviruses and parechoviruses are

*References 28,275,357,359–363,382,383.

†References 21,189,277,364,382,384–388.

now diagnosed by PCR, however, and serotype information is unavailable. Because of this, much of the specific information in this section was determined more than 2 decades ago. In recent years, phenotypic presentations have been altered by recombination between different enteroviruses, and clinical characteristics of specific enterovirus types today may be different from the findings identified 4 or 5 decades ago.

## ABORTION

### Polioviruses

Poliomyelitis is associated with an increased incidence of abortion. Horn [121] reported 43 abortions in 325 pregnancies complicated by maternal poliomyelitis. Abortion was directly related to the severity of the maternal illness, including the degree of fever during the acute phase of illness. Abortion also was associated with mild, nonparalytic poliomyelitis, however. Schaeffer and colleagues [136] studied the placenta and abortus 12 days after the onset of illness in a mother. Poliovirus type 1 was isolated from the placenta and the fetal tissues.

Other investigators [391,393–396] have reported an increased incidence of abortions in cases of maternal poliomyelitis. Siegel and Greenberg [140] noticed that fetal death occurred in 14 (46.7%) of 30 instances of maternal poliomyelitis during the first trimester. Kaye and colleagues [397] reviewed the literature in 1953 and found 19 abortions in 101 cases of poliomyelitis in pregnancy. In a small study in Evanston Hospital in Illinois, the abortion rate associated with maternal poliomyelitis was similar to the expected rate [395]. In a study of 310 pregnant women who received trivalent oral poliovirus vaccine, there was no increase in abortions beyond the expected rate [146]. In a later study in Finland that involved about 9000 pregnant women immunized with oral poliovirus vaccine, there was no evidence of an increase in stillbirths [398].

### Coxsackieviruses

Although in the late 1950s and early 1960s there were extensive outbreaks of illness caused by coxsackievirus A16, there was no evidence of adverse outcomes of pregnancy related to this virus. Because infections with other coxsackieviruses rarely involve large segments of the population, rate studies have not been performed.

Frisk and Diderholm [399] found that 33% of women with abortions had IgM antibody to coxsackievirus B strains, whereas only 8% of controls had similar antibody. In a second, larger study, the same research group confirmed their original findings [400].

### Echoviruses

There is no available evidence suggesting that echovirus infections during pregnancy are a cause of spontaneous abortion. Landsman and associates [184] studied 2631 pregnancies during an epidemic of echovirus 9 and could find no difference in antibody to echovirus 9 between mothers who aborted and mothers who delivered term infants. A similar study in Finland revealed no increase in the abortion rate among mothers infected in early pregnancy with echovirus 9 [185].

## CONGENITAL MALFORMATIONS

### Polioviruses

In the Collaborative Perinatal Research Project sponsored by the National Institutes of Health comprising 45,000 pregnancies, the congenital malformation rate associated with poliovirus infection was 4.1% [401]. Although isolated instances of congenital malformation and maternal poliomyelitis have been reported, there is little statistical evidence showing that polioviruses are teratogens. In their review of the literature, Kaye and colleagues [397] identified six anomalies in 101 infants born to mothers with poliomyelitis during pregnancy. In the reviews of Horn [121], Bates [127], and Siegel and Greenberg [140] there was no evidence of anomalies induced by maternal poliovirus infection.

The possibility of congenital anomalies associated with attenuated oral poliovirus vaccine has also been studied [145,146,397,401–403]. Pearson and coworkers [145] studied the fetal malformation rate in a community in which a large vaccine field trial had been done; although it is probable that pregnant women became infected with vaccine virus by secondary spread, there was no community increase in fetal malformations. Prem and associates [146] studied the infants of 69 women who received attenuated vaccine before 20 weeks of gestation and found that none had anomalies. In contrast, the rate of congenital defects in Blackburn, England, increased coincident with mass vaccination with trivalent poliomyelitis vaccine [402]. There is no evidence of cause and effect related to this observation, however. Connelly and colleagues [403] commented on a child with a unique renal disease acquired in utero. The child's mother had received oral polio vaccine during the 2nd month of pregnancy.

In February 1985, a mass vaccination program with live oral poliovirus vaccine was carried out in Finland [404]. Although pregnant women received vaccine, there was no evidence that vaccine virus had a harmful effect on developing fetuses.

### Coxsackieviruses

In large prospective studies, Brown [405–407] and others [408–410] made a serologic search for selected maternal enterovirus infections in association with congenital malformations. In one study, serum samples from 22,935 women had been collected [410]. From this group, serum samples from 630 mothers of infants with anomalies and from 1164 mothers of infants without defects were carefully studied. Specifically, serologic evidence was sought for infection during the first trimester and last 6 months of pregnancy with coxsackieviruses B1 through B5 and A9 and with echoviruses 6 and 9. In this study, infants were examined for 113 specific abnormalities; these anomalies were grouped into 12 categories for analysis.

The investigators showed a positive correlation between maternal infection and infant anomaly with coxsackieviruses B2 through B4 and A9. The overall

first-trimester infection rate with coxsackievirus B4 was significantly higher in patients with anomalies than in controls. Maternal coxsackievirus B2 infection throughout pregnancy, coxsackievirus B4 infections during the first trimester of pregnancy, and infection with at least one of the five coxsackievirus B strains during pregnancy all were associated with urogenital anomalies. Coxsackievirus A9 infection was associated with digestive anomalies, and coxsackieviruses B3 and B4 were associated with cardiovascular defects. When coxsackievirus B strains were analyzed as a group (B1 to B5), there was an overall association with congenital heart disease; the likelihood of cardiovascular anomalies was increased when maternal infection with two or more coxsackievirus B strains occurred.

In this study, the mothers had been instructed to keep illness diary sheets. There was no correlation between reported maternal clinical illnesses and serologic evidence of infection with the selected enteroviruses. This lack of correlation suggests that many infections that may have been causally related to the anomalies were asymptomatic. A disturbing finding in this study was the lack of seasonal occurrence of the births of children with specific defects. Because enterovirus transmission is most common in the summer and fall, the birth rate of children with malformations should have been greatest in the spring and summer if coxsackieviruses were a major cause of malformation.

In the Collaborative Perinatal Research Project sponsored by the National Institutes of Health, Elizan and coworkers [411] were unable to find any relationships between maternal infections with coxsackievirus B strains and congenital CNS malformations. Scattered case reports in the literature describe congenital anomalies associated with maternal coxsackievirus infections. Makower and colleagues [176] reported a child with congenital malformations who was born at 32 weeks' gestation and from whom a coxsackievirus A4 strain was recovered from the meconium. The child's mother had been well throughout pregnancy except for a febrile illness during the 1st month. The relationship of the viral infection to the congenital malformations or to the prematurity is uncertain.

Gauntt and associates [412] studied ventricular fluids from 28 newborn infants with severe congenital anatomic defects of the CNS. In four infants (two with hydranencephaly, one with an occipital meningocele, and one with aqueductal stenosis), neutralizing antibody to one or more coxsackievirus B types was found in the fluid. In one case, IgM-neutralizing antibody to coxsackievirus B6 was found. The investigators concluded that their data suggested the possibility of an association between congenital infections with coxsackievirus B strains and severe CNS defects.

### Echoviruses

In the large prospective study of Brown and Karunas [410], the possible association of maternal infections with echoviruses 6 and 9 and congenital malformations was examined. Maternal infection with these selected echoviruses apparently was not associated with any anomaly. In three other studies [183–185], no association was found between maternal echovirus 9 infection and congenital malformation.

## PREMATURITY AND STILLBIRTH

### Polioviruses

In the study by Horn [121] of 325 pregnancies, nine infants died in utero. In each instance, the mother was critically ill with poliomyelitis. Horn [121] also observed that 45 infants weighed less than 6 lb, and 17 of these had a birth weight of less than 5 lb. These low birth weight infants were born predominantly to mothers who had had poliomyelitis early in pregnancy. Aycock [124,413] reported a similar finding. In New York City, Siegel and Greenberg [140] also documented an increase in prematurity after maternal poliomyelitis infection. This increase was specifically related to maternal paralytic poliomyelitis. There has been no observation of stillbirth or prematurity in relation to vaccine administration [398].

### Coxsackieviruses

Bates [171] reported a fetus of 8 months' gestational age who was stillborn and had calcific pancarditis and hydrops fetalis at autopsy. Fluorescent antibody study revealed coxsackievirus B3 antigen in the myocardium. Burch and colleagues [179] described three stillborn infants who had fluorescent antibody evidence of coxsackievirus B myocarditis, one each with coxsackieviruses B2, B3, or B4. They also reported a premature boy who had histologic and immunofluorescent evidence of cardiac infection with coxsackieviruses B2 through B4; he lived only 24 hours. A macerated stillborn girl was delivered 2 weeks after the occurrence of aseptic meningitis caused by coxsackievirus A9 in a 27-year-old woman [333]. Virus was recovered from the placenta, but not from the infant. Coxsackievirus B6 has been recovered from the brain, liver, and placenta of a stillborn infant [170]. An infant of 26 weeks' gestation with nonimmune hydrops fetalis with an intrauterine infection with coxsackievirus B3 was reported by Ouellet and coworkers [414].

### Echoviruses and Enteroviruses

Freedman [415] reported the occurrence of a full-term, fresh stillbirth in a woman infected with echovirus 11. Because the infant had no pathologic or virologic evidence of infection, the stillbirth was attributed to a secondary consequence of maternal infection from fever and dehydration, rather than primary transplacental infection. Echovirus 27 has been associated with intrauterine death on two occasions [170,416].

In an extensive study of neonatal enterovirus infections in Milwaukee in 1979, Piraino and associates [383] found that 12 of 19 stillbirths occurred from July through October coincident with a major outbreak of enterovirus disease. Echovirus 11 was the main agent isolated during this period. A 1300-g fetus, stillborn after 26 weeks' gestation, had hydrocephalus, fibrotic peritonitis, and hepatosplenomegaly and was found to have enterovirus 71 infection by PCR and immunohistochemical study [190].

# NEONATAL INFECTION

## Nonpolio Enteroviruses and Parechoviruses

Illnesses caused by nonpolio enteroviruses and parechoviruses are discussed by clinical classification (Table 24–5) in the following sections.

### *Inapparent Infection*

Although it is probable that inapparent infections in neonates occasionally occur with many different enteroviruses, and parechoviruses, there is little documentation of this assumption. Cherry and coworkers [174] studied 590 normal newborns during a 6-month period and found only one infection without clinical signs of illness. This was a child infected in utero or immediately thereafter with coxsackievirus B2. The mother had an upper respiratory illness 10 days before delivery. In a similar but more comprehensive study, Jenista and associates [201] failed to isolate any enteroviruses from cultures from 666 newborns on the 1st postpartum day. During weekly cultures during the month after birth, 75 enteroviruses were isolated, however. Symptomatic enterovirus disease occurred in 21% (16 of 75).

During a survey of perinatal virus infections, 44 infants were found to be infected with parechovirus 1 during the study period May to December 1966 [270]. The virus prevalence and the incidence of new infections during this period were fairly uniform. No illness was attributed to parechovirus 1 infection, and the virus disappeared from the nursery in mid-December 1966. Inapparent infections with parechovirus 1 have been reported on two other occasions [259,280]. Infections without evidence of illness have occurred with coxsackieviruses A9, B1, B4, and B5 and with echoviruses 3, 5, 9, 11, 13, 14, 20, 30, and 31.*

### *Mild, Nonspecific Febrile Illness*

In a review of 338 enterovirus infections in early infancy, 9% were classified as nonspecific febrile illnesses [420]. Illness may be sporadic in nature or part of an outbreak with a specific viral type. In the latter situation, clinical manifestations vary depending on the viral type; some infants have aseptic meningitis and other signs and symptoms, and some have only nonspecific fever. Viral types most commonly found in nonspecific fevers were coxsackievirus B5 and echoviruses 5, 11, and 33; other agents identified have included coxsackieviruses A9, A16, and B1 through B4 and echoviruses 4, 7, 9, and 17.† A 6-day-old infant with parechovirus 4 and fever and poor feeding has been described [424].

Mild, nonspecific febrile illness occurs most commonly in full-term infants after uneventful pregnancies and deliveries without complications. Illness can occur at any time during the 1st month of life. When the onset occurs after the infant is 7 days old, a careful history frequently reveals a trivial illness in a family member. The onset of illness is characterized by mild irritability and fever (usually 38° C to 39° C, but higher temperatures occasionally occur). Poor feeding is frequently observed. One or two episodes of vomiting or diarrhea or both may occur in some infants. The usual duration of illness is 2 to 4 days.

Routine laboratory study is not helpful, but cerebrospinal fluid (CSF) examination may reveal an increased protein concentration and leukocyte count indicative of aseptic meningitis. Although illness in this category is mild by definition, the degree of viral infection may be extensive. When looked for, virus may be isolated from the blood, urine, and CSF of infants with mild illnesses [234,417].

### *Sepsis-like Illness*

The major diagnostic problem in neonatal enterovirus infections is differentiation of bacterial from viral disease. Even in an infant with mild, nonspecific fever, bacterial disease must be strongly considered. The sepsis-like illness described here is always alarming. This illness is characterized by fever, poor feeding, abdominal distention, irritability, rash, lethargy, and hypotonia [339, 381–383]. Other findings include diarrhea, vomiting, seizures, shock, disseminated intravascular coagulation, thrombocytopenia, hepatomegaly, jaundice, and apnea. The onset of illness is heralded by irritability, poor feeding, and fever; other manifestations follow within 24 hours. In a group of 27 neonates, Lake and associates [427] observed that 54% had temperatures of 39° C or greater. The duration of fever varies from 1 to 8 days (most commonly 3 to 4 days). Barre and colleagues [426] reported a 3-day-old boy with an enterovirus-associated hemophagocytic syndrome. This neonate presented with a typical sepsis-like picture with fever, hepatosplenomegaly, coagulopathy, thrombocytopenia, and anemia. The child recovered and had no hemophagocytic relapses.

Sepsis-like illness is common. Morens [420] described its occurrence in one fifth of 338 enterovirus infections in infants. In an attempt to differentiate bacterial from viral disease, Lake and associates [427] studied 27 infants with enterovirus infections. White blood cell counts were not helpful because the total count, the number of neutrophils, and the number of band form neutrophils were elevated in most instances. Historical data were most important. Most mothers had evidence of a recent febrile, viral-like illness. Other factors often associated with bacterial sepsis, such as prolonged rupture of membranes, prematurity, and low Apgar scores, were unusual in the enterovirus infection group.

Sepsis-like illness has been identified most often with coxsackieviruses B2 through B5; echovirus types 5, 11, and 16; and parechovirus 3. Other viruses detected include coxsackieviruses A9 and B1; echoviruses 2, 3, 4, 6, 9, 14, 19, and 21; and parechovirus 1.* Since the early 1980s, echovirus 11 has been associated most frequently with fatal septic events, hepatic necrosis, and disseminated intravascular coagulation.†

### Respiratory Illness

Respiratory complaints are generally overshadowed by other manifestations of neonatal disease caused by enteroviruses and parechoviruses. Only 7% of 338 enterovirus infections in early infancy were classified as respiratory illness [420]. Respiratory illness associated with enteroviruses has been sporadic except for illnesses associated with echovirus 11 and parechovirus 1 [259,269].

Hercík and coworkers [269] reported an epidemic of respiratory illness in 22 newborns associated with echovirus 11 infection. All of these infants had rhinitis and pharyngitis, 50% had laryngitis, and 32% had interstitial pneumonitis. Berkovich and Pangan [259] studied respiratory illnesses in premature infants and reported 64 with illness, 18 of whom had virologic or serologic evidence of parechovirus 1 infection. Many other infants had high but constant levels of serum antibody to parechovirus 1. The infants with proven parechovirus 1 infections could not be clinically differentiated from infants without evidence of parechovirus 1 infection. Of the infants, 90% had coryza, and 39% had radiographic evidence of pneumonia. Respiratory tract symptoms were noted in about half of the neonates in two parechovirus studies in the Netherlands [429,444].

#### Herpangina

Chawareewong and associates [445] described several infants with herpangina and coxsackievirus A5 infection. A vesicular lesion on an erythematous base on a tonsillar pillar in a 6-day-old infant with coxsackievirus B2 meningitis has also been reported [446]. Two 1-month-old infants were described in an outbreak of herpangina owing to coxsackievirus B3 in a welfare home in Japan [447].

#### Coryza

Several agents have been associated with coryza: coxsackievirus A9; echoviruses 11, 17, and 19; and parechoviruses 1 and 3 [188,269,280,283,426].

#### Pharyngitis

Pharyngitis is uncommon in neonatal enterovirus infections. In more than 50 infants with enterovirus infections studied by Linnemann and colleagues [437] and Lake and associates [427], pharyngitis did not occur. Suzuki and coworkers [448] observed pharyngitis in 3 of 42 neonates with echovirus 11 infections. In contrast, in the same study, 67% of children 1 month to 4 years old had pharyngitis. Pharyngitis has been associated with coxsackievirus B4 and with echoviruses 11, 17, and 18 [247,269,273,434,438].

#### Laryngotracheobronchitis or Bronchitis

A few enteroviruses have been identified in cases of laryngotracheobronchitis or bronchitis: coxsackieviruses B1 and B4 and echovirus 11 [269,449]. Specific clinical descriptions of laryngotracheobronchitis or bronchitis associated with enterovirus infections are scarce. Hercík and coworkers [269] observed laryngitis in 11 and croup in 4 of 22 neonates during an echovirus 11 outbreak. All of the affected infants had upper respiratory tract findings, vomiting, and lethargy. Many were also cyanotic and had hepatosplenomegaly.

#### Pneumonia

Pneumonia as the main manifestation of neonatal enterovirus and parechovirus infections is rare. Morens [420] documented only seven instances of pneumonia in 338 neonatal enterovirus infections. Outbreaks of pneumonia in neonates have been reported with echovirus 11 and parechovirus 1 [259,269]. Pneumonia resulting from other enteroviruses is a sporadic event and has been reported for the following nonpolio enteroviruses: coxsackieviruses A9 and B4 and echoviruses 9, 17, and 31.

During a nursery outbreak of echovirus 11, 7 of 22 neonates had pneumonia [269]. All infants had signs of upper respiratory infection and general signs of sepsis-like illness. In infants with pneumonia associated with a nursery epidemic of parechovirus 1, coryza, cough, and dyspnea were early signs [259]. The illnesses tended to be protracted, with radiographic changes persisting for 10 to 100 days.

#### Cloud Baby

Eichenwald and associates [264] recovered echovirus 20 from four full-term infants younger than 8 days. Although these infants apparently were well, it was found that they were extensively colonized with staphylococci and that they disseminated these organisms into the air around them. Because of this ability to disseminate staphylococci, they were called "cloud babies." The investigators believed that these cloud babies contributed to the epidemic spread of staphylococci in the nursery. Because active staphylococcal dissemination occurred only during the time that echovirus 20 could be recovered from the nasopharynx, it was theorized that viral-bacterial synergism occurred.

### Gastrointestinal Manifestations

#### Vomiting or Diarrhea

Vomiting and diarrhea are common but usually just part of the overall illness complex and not major manifestations. In 1958, Eichenwald and colleagues [263] described epidemic diarrhea associated with echovirus 18 infections.

In 22 infants with epidemic respiratory disease caused by echovirus 11, all had vomiting as a manifestation of the illness [269]. Linnemann and colleagues [437] reported vomiting in 36% and diarrhea in 7% of neonates with echovirus infections. In another study, Lake and associates [427] found diarrhea in 81% and vomiting in 33% of neonates with nonpolio enterovirus infections. Vomiting and diarrhea in neonates have been associated with coxsackieviruses B1, B2, and B5; echoviruses 4 through 6, 8, 9, 11, 16 through 19, and 21; parechoviruses 1 and 3; and enterovirus 71.*

*References 187,234,240,257,258,263,265,266,269,276,283,436,437,450–452.

### Hepatitis

Morens [420] observed that 2% of neonates with clinically severe enterovirus disease had hepatitis. Lake and associates [427] found that 37% of neonates with enterovirus infections had hepatomegaly, and hepatosplenomegaly was observed by Hercík and coworkers [269] in 12 of 22 newborns with echovirus 11 respiratory illnesses.

Severe hepatitis, frequently with hepatic necrosis, has been associated with echoviruses 5, 6, 7, 9, 11, 14, 19, 20, 21, and 30.* In 1980, Modlin [277] reported four fatal echovirus 11 illnesses in premature infants. All had hepatitis, disseminated intravascular coagulation, thrombocytopenia, lethargy, poor feeding, and jaundice. Since 1980, there have been many reports of sepsis-like illness with fatal hepatitis related to echovirus 11.†

Coxsackieviruses B1, B3, and B4 and other B types have been associated with neonatal hepatitis.‡ Abzug [455] reviewed medical records of 16 neonates with hepatitis and coagulopathy and found a case-fatality rate of 31%. All of the five patients who died had myocarditis, and three had encephalitis. Although sepsis-like illness frequently occurs in infections with parechovirus, hepatitis is relatively uncommon [34,35,424].

### Pancreatitis

Pancreatitis was recognized in three of four newborns with coxsackievirus B5 meningitis [238] and in coxsackieviruses B3 and B4 infections at autopsy [254]. In other fatal coxsackievirus B infections, pancreatic involvement has been identified, but clinical manifestations have rarely been observed.

### Necrotizing Enterocolitis

Lake and associates [427] described three infants with necrotizing enterocolitis. Coxsackievirus B3 was recovered from two of these infants, and coxsackievirus B2 was recovered from the third. Parechovirus 1 was associated with an outbreak of necrotizing enterocolitis [456].

## Cardiovascular Manifestations

In contrast with enterovirus cardiac disease in children and adults, in which pericarditis is common, neonatal disease virtually always involves the heart muscle.§ Most cases of neonatal myocarditis are related to coxsackievirus B infections, and nursery outbreaks have occurred on several occasions. In 1961, Kibrick [26] reviewed the clinical findings in 45 cases of neonatal myocarditis; his findings are summarized in Table 24–6. Many early experiences, particularly in South Africa, involved catastrophic nursery epidemics. Since the observation in 1972 of five newborns with echovirus 11 infections and myocarditis, there have been no further reports of nursery epidemics [459].

| Hepatosplenomegaly | 53 |
| Biphasic course | 35 |
| Central nervous system signs | 27 |
| Hemorrhage | 13 |
| Jaundice | 13 |
| Diarrhea | 8 |

*Modified from Kibrick S. Viral infections of the fetus and newborn. Perspect Virol 2:140, 1961.*

The illness as described by Kibrick [26] most commonly had an abrupt onset and was characterized by listlessness, anorexia, and fever. A biphasic pattern was observed in about one third of the patients. Progression was rapid, and signs of circulatory failure appeared within 2 days. If death did not occur, recovery was occasionally rapid, but usually occurred gradually during an extended period. Most patients had cardiac findings, such as tachycardia, cardiomegaly, electrocardiogram (ECG) changes, and transitory systolic murmurs. Many patients showed signs of respiratory distress and cyanosis. About one third of infants had signs suggesting neurologic involvement. Of the 45 patients analyzed by Kibrick [26], only 12 survived.

In the nursery outbreak of echovirus 11 reported by Drew [460], 5 of 10 infants had tachycardia out of proportion to fevers. Three of these infants had ECGs; supraventricular tachycardia occurred in all, and ST segment depression was observed in two. Supraventricular tachycardia has also been seen in patients with coxsackievirus B infections [233]. Echovirus 19 has been associated with myocarditis [465].

Until more recently, neonatal myocarditis related to enteroviruses was less common than it was 5 decades ago. In his review in 1978, Morens [420] reported only two instances among 248 severe neonatal enterovirus illnesses. In 2007, severe neonatal disease associated with coxsackievirus B1 infection was noted in several areas of the United States [315]. In Los Angeles County, California, 12 neonates had myocarditis. Similarly, in Chicago, Illinois, 11 neonates ranging in age from less than 1 to 12 days had myocarditis. Other cases with coxsackievirus B1 myocarditis occurred in Alaska and Colorado.

## Exanthem

Exanthem as a manifestation of neonatal infections with enteroviruses and parechoviruses has occurred with coxsackieviruses B1, B3, and B5; echoviruses 4, 5, 7, 9, 11,

16, 17, 18, and 21; and parechoviruses 1 and 3.* In most instances, rash is just a minor manifestation of moderate to severe neonatal disease. Of 27 infants studied by Lake and associates [427], 41% had exanthem. Similarly, Linnemann and colleagues [437] reported exanthem in 4 of 14 neonates with echovirus infections.

Cutaneous manifestations usually occur between the 3rd and 5th days of illness. The rash is usually macular or maculopapular, and petechial lesions occasionally are seen. Vesicular lesions have been reported only once with coxsackievirus B3 infection and once with enterovirus 71 infection in neonates. Theodoridou and associates [470] described a full-term newborn boy with vesicular lesions at birth. PCR revealed coxsackievirus B3. A 1-month-old infant with enterovirus 71 infection and hand-foot-and-mouth syndrome has been reported [471]. Hall and associates [436] reported two neonates with echovirus 16 infections in which the illnesses were similar to roseola. The patients had fevers for 2 and 3 days, defervescence, and then the appearance of maculopapular rashes.

### Neurologic Manifestations

#### Meningitis and Meningoencephalitis

As shown in Table 24–5, meningitis and meningoencephalitis have been associated with coxsackieviruses B1 through B5, many echoviruses, and parechoviruses.† In most instances, the differentiation of meningitis from meningoencephalitis is difficult in neonates. Meningoencephalitis is common in infants with sepsis-like illness, and autopsy studies reveal many infants with disseminated viral disease (e.g., heart, liver, adrenals) in addition to CNS involvement. In the review of Morens [420], 50% of the neonates with enterovirus infections had encephalitis or meningitis.

The initial clinical findings in neonatal meningitis or meningoencephalitis are similar to findings in nonspecific febrile illness or sepsis-like illness. Most often, the child is normal and then becomes febrile, anorectic, and lethargic. Jaundice frequently affects newborns, and vomiting occurs in neonates of all ages. Less common findings include apnea, tremulousness, and general increased tonicity. Seizures occasionally occur.

CSF examination reveals considerable variation in protein, glucose, and cellular values. In seven newborns with meningitis related to coxsackievirus B5 studied by Swender and associates [257], the mean CSF protein value was 244 mg/dL, and the highest value was 480 mg/dL. The mean CSF glucose value was 57 mg/dL, and one of the seven newborns had pronounced hypoglycorrhachia (12 mg/dL). The mean CSF leukocyte count for the seven infants was 1069 cells/mm$^3$, with 67% polymorphonuclear cells. The highest cell count was 4526 cells/mm$^3$, with 85% polymorphonuclear cells. In another study involving 28 children younger than 2 months in whom coxsackievirus B5 was the implicated pathogen, 36% of the infants had CSF leukocyte counts of 500 cells/mm$^3$ or greater [438]. In this same study, only 13% of the infants had CSF protein values of 120 mg/dL or greater; 12% of the infants had glucose values of less than 40 mg/dL.

The CSF findings in cases of neonatal nonpolio enterovirus and parechovirus infections are frequently similar to CSF findings in bacterial disease. In particular, the most consistent finding in bacterial disease, hypoglycorrhachia, affects about 10% of newborns with enterovirus meningitis [257,418,450,452,493].

#### Paralysis

Johnson and associates [484] reported a 1-month-old boy with right facial paralysis and loss of abdominal reflexes. The facial paralysis persisted through convalescence; the reflexes returned to normal within 2 weeks. The boy was infected with coxsackievirus B2. A 1-month-old boy with hand-foot-and-mouth syndrome and bilateral lower limb weakness owing to enterovirus 71 infection has been described [471].

### Sudden Infant Death

Balduzzi and Greendyke [379] recovered coxsackievirus A5 from the stool of a 1-month-old infant after sudden infant death. In a similar investigation of sudden infant death, Gold and coworkers [380] recovered coxsackievirus A4 from the brains of three infants. Coxsackievirus A8 was recovered from the stool of a child in whom anorexia was diagnosed on the day before death. Coxsackievirus B3 was recovered at autopsy from an infant who died suddenly on the 8th day of life [379]. Morens and associates [10] reported eight cases of sudden infant death associated with enterovirus infection; parechovirus 1 was found on two occasions. In five instances of cot death in one study, echovirus 11 was isolated from the lungs in two infants, from the myocardium in one, and from the nose or feces in the other two [357].

Grangeot-Keros and coworkers [494] looked for evidence of enterovirus infections using PCR and an IgM immunoassay in cases of sudden and unexplained infant deaths. They divided their infant death population into two groups. One group had clinical, biologic, or histologic signs of viral infection, and the other group had no indicators of an antecedent infection. Of infants with evidence of a preceding infection, 54% had PCR evidence of an enterovirus in samples from the respiratory tract or lung or both, whereas none of the infants without evidence of a prior infection had similar positive PCR findings. Their IgM antibody studies supported their PCR findings.

## Manifestations of Polioviruses

### General Considerations

Infection with poliovirus in children classically results in a spectrum of clinical illness. As described by Paul [495] and accepted by others, 90% to 95% of infections in children after the neonatal period are inapparent, 4% to 8% are abortive, and 1% to 2% are frank cases of poliomyelitis. Whether neonatal poliovirus infection is acquired in

*References 25,27,34,35,177,188,219,221,243,261,266,276,283,356,383,390,430, 435–437,459,465–470.

†References 25,27,28,34,35,179,187,224,243,258,261,265,275,276,284,315,321, 361,366,381, 383,418,419,429,438,440,446,450,451,453,456,458,459,466,468, 471–491.

utero, during birth, or after birth, the more severe manifestations of clinical illness seem to be similar to those of older children. Available reports in the literature suggest, however, that the frequencies of occurrence of inapparent, abortive, and frank cases are quite different from older children. Most reports describe severely affected infants [123,125–137,139–141,143,144]. Asymptomatic infection does occur, however [124,138].

In the excellent review by Bates [127] in 1955, 58 cases of clinically overt poliomyelitis in infants younger than 1 month were described. Although complete data were unavailable on many of the cases, 51 had paralysis or died from their disease, or both. Of the total number of infants for whom there were clinical data, only one had nonparalytic disease. Because follow-up observation was recorded for only a short time in many infants, the evaluation of residual paralysis (presence or absence) may be unreliable. Pertinent clinical data from the study by Bates are presented in Table 24–7; these data show that more than half of the cases resulted from maternal disease. Because others have identified congenital infection without symptomatic maternal infection, it is probable that infection in the mothers was the source for an even greater percentage of the neonatal illnesses. Because the incubation period of neonatal poliomyelitis has not been determined, it is difficult to know how many infants were infected in utero. Most illnesses occurring within the first 5 days of life probably were congenital. Most neonates had symptoms of fever, anorexia or dysphagia, and listlessness. Almost half of the infants described in this review died, and of those surviving, 48% had residual paralysis.

**TABLE 24–7** Clinical Findings in 58 Cases of Neonatal Poliomyelitis

| Finding | No. Cases with Particular Finding/ No. Cases Evaluated (%) |
|---|---|
| **Time of Onset after Birth** | |
| ≤5 days | 13/55 (24) |
| 6-14 days | 25/55 (45) |
| ≥15 days | 17/55 (31) |

*Adapted from Bates T. Poliomyelitis in pregnancy, fetus, and newborn. Am J Dis Child 90:189, 1955.*

### Inapparent Infection

Shelokov and Habel [138] followed a virologically proven infected newborn without signs of illness. The infant was normal when 1 year old. Wingate and coworkers [142] studied an infant delivered by cesarean section from a woman with poliomyelitis who died 1 hour after delivery. Her infant was treated with gamma globulin intramuscularly at the postnatal age of 21 hours. The infant boy remained asymptomatic; poliovirus 1 was recovered from a stool specimen on the 5th day of life.

### Infection Acquired In Utero

Elliott and colleagues [130] described an infant girl in whom "complete flaccidity" was observed at birth. The infant's mother had had mild paralytic poliomyelitis, with the onset of minor illness occurring 19 days before the infant's birth. Fetal movements had ceased 6 days before delivery, suggesting that paralysis had occurred at this time. On examination, the infant was severely atonic; when supported under the back, she was passively opisthotonic. Respiratory efforts were abortive and confined to accessory muscles, and laryngoscopy revealed complete flaccidity in the larynx.

Johnson and Stimson [132] reported a case in which the mother's probable abortive infection occurred 6 weeks before the birth of the infant. The newborn was initially thought to be normal, but apparently had no medical examination until the 4th day of life. At that time, the physician diagnosed a right hemiplegia. The next day, a more complete examination revealed lateral bulging of the right abdomen accompanied by crying and the maintenance of the lower extremities in a frog-leg position. Adduction and flexion at the hips were weak, and knee and ankle jerks were absent. Laboratory studies were unremarkable except for the examination of the CSF, which revealed 20 lymphocytes/mm$^3$ and a protein concentration of 169 mg/dL. During a 6-month period, the child's paralysis gradually improved and resulted in only residual weakness of the left lower extremity.

Paresis of the left arm occurred in another child with apparent transplacentally acquired poliomyelitis shortly after birth [135]. The 2-day-old infant was quadriplegic, but patellar reflexes were present, and there were no respiratory or swallowing difficulties. This child had pneumonia when 3 weeks old, but general neurologic improvement occurred. Examination when the infant was 8 weeks old revealed bilateral atrophy of the shoulder girdle muscles. The CSF in this case revealed 63 leukocytes/mm$^3$, with 29% polymorphonuclear cells, and a protein value of 128 mg/dL. All three of the above-described infants were apparently infected in utero several days before birth. Their symptoms were exclusively neurologic; fever, irritability, and vomiting did not occur.

### Postnatally Acquired Infection

In contrast to infections acquired in utero, infections that are acquired postnatally are more typical of classic poliomyelitis. Shelokov and Weinstein [139] described an infant who was asymptomatic at birth. Onset of minor symptoms in the mother occurred 3 weeks before

delivery, and major symptoms occurred 1 day before delivery. On the 6th day of life, the infant became suddenly ill with watery diarrhea. He looked grayish and pale. The next day, he was irritable, lethargic, and limp and had a temperature of 38° C. Mild opisthotonos and weakness of both lower extremities developed. He was responsive to sound, light, and touch. The CSF had an elevated protein level and an increased number of leukocytes. His condition worsened over 3 days, and then gradual improvement began. At 1 year, he had severe residual paralysis of the right leg and moderate weakness in the left leg.

Baskin and associates [126] described two infants with neonatal poliomyelitis. The first infant, whose mother had severe poliomyelitis at the time of delivery, was well for 3 days and then developed a temperature of 38.3° C. On the 5th day of life, the boy became listless and cyanotic. CSF examination revealed a protein level of 300 mg/dL and 108 leukocytes/$mm^3$. His condition worsened, and extreme flaccidity, irregular respiration, and progressive cyanosis developed; he died on the 7th day of life. The second infant was a boy who was well until he was 8 days old; he then became listless and developed a temperature of 38.3° C. During the next 5 days, he developed flaccid quadriplegia; irregular, rapid, and shallow respirations; and an inability to swallow. He died on the 14th day of life. His mother had developed acute poliomyelitis 6 days before the onset of his symptoms.

Abramson and colleagues [123] reported four children with neonatal poliomyelitis, two of whom died. In three of the children, the illnesses were typical of acute poliomyelitis seen in older children; they were similar to the cases of Baskin and associates [126] described previously. The fourth child died at 13 days of age with generalized paralysis. The onset of his illness was difficult to define, and he was never febrile. Swarts and Kercher [141] also described an infant whose illness had an insidious onset. When 10 days old, the infant gradually became lethargic and anorectic and regurgitated formula through his nose. On the next day, flaccid quadriplegia developed. Winsser and associates [143] and Bates [127] reported infants with acute poliomyelitis with clinical illnesses similar to illnesses that occur in older individuals.

### Vaccine Viral Infections

Oral polio vaccines have been administered to newborns in numerous studies [146,202–214]. Vaccine viral infection occurs in newborns with all three types of poliovirus, although the rate of infection is less than for immunized older children. This rate is governed by the dose of virus, transplacentally acquired maternal antibody, and antibody acquired from colostrum and breast milk. Although clinical illness rarely has resulted from attenuated poliovirus in older children and adults, there is only one specific report of paralytic poliomyelitis in a newborn associated with infection with a vaccine viral strain [215]. In that case, the possible source for the infection was the recently vaccinated child of the babysitter. In a review of 118 cases of vaccine-associated paralytic poliomyelitis in the United States from 1980–1992, the age of patients ranged from 1 month to 69 years, but details about neonates were not presented [496].

## Manifestations of Specific Nonpolio Enteroviruses

### Coxsackieviruses

#### Coxsackievirus A

There have been few reports of neonatal coxsackievirus A infections. Baker and Phillips [378] reported an infant small for gestational age with pneumonia and a sepsis-like illness with disseminated intravascular coagulation. This newborn died on the 2nd day of life, and culture of CSF grew coxsackievirus A3. Balduzzi and Greendyke [379] recovered coxsackievirus A5 from the stool of a 1-month-old infant with sudden infant death. In a similar investigation of sudden infant death, Gold and coworkers [380] recovered coxsackievirus A4 from the brains of three infants. Coxsackievirus A8 was also recovered from the stool of a child in whom anorexia was observed on the day before death. Berkovich and Kibrick [258] reported a 3-day-old neonate with nonspecific febrile illness (38.3° C) who was infected with coxsackievirus A9. Coxsackievirus A9 was also recovered from an 11-day-old infant with rhinitis, lethargy, anorexia, and fever [283]. This illness lasted 3 days. Jack and associates [270] described a 3-day-old newborn with fever, cyanosis, and respiratory distress who died on the 7th day of life; an autopsy revealed bronchopneumonia. Coxsackievirus A9 was isolated from the feces on the 4th and 6th days of life.

Lake and associates [427] reported two neonates with coxsackievirus A9 infections, but no clinical details were presented. Jenista and coworkers [201] recovered coxsackievirus A9 strains from seven nonhospitalized neonates who were thought to be well. In the Netherlands, a neonate with coxsackievirus A9 illness had pericarditis, meningitis, pneumonitis, and hepatitis; he recovered completely [464]. Krajden and Middleton [27] described a neonate with a sepsis-like illness who died. Coxsackievirus A9 was recovered from the liver and lung. Morens [420] also reported a death associated with this same virus type. Eisenhut and associates [381] reported an outbreak that included four neonates with coxsackievirus A9 infections. One infant who had meningitis, myocarditis, and disseminated intravascular coagulation died. A second neonate had vomiting, rhinitis, and abdominal distention, and two neonates had asymptomatic infections.

Of 598 neonates admitted to a regular nursery in Bangkok, Thailand, in spring 1977, 48 had herpangina [381]. Coxsackievirus A5 was isolated from nine specimens from the affected infants, and an increase in the serum antibody titer was identified in 10 instances. Helin and colleagues [483] described 16 newborns with aseptic meningitis caused by coxsackievirus A14. During a 2.5-year follow-up period, they all developed normally, and no sequelae were identified. Coxsackievirus A16 was recovered from one newborn with nonspecific illness; his mother had had hand-foot-and-mouth syndrome 4 days previously [483].

#### Coxsackievirus B1

Until more recently, coxsackievirus B1 was only occasionally recovered from newborns (Table 24–8). Eckert and coworkers [449] recovered a coxsackievirus B1 strain from the stool of a 1-month-old boy with bronchitis. Jahn and

Cherry [234] described a 4-day-old infant who became febrile and lethargic. This illness persisted for 5 days without other signs or symptoms. An examination of the CSF showed a slight increase in the number of leukocytes, and most were mononuclear cells. Coxsackievirus B1 was recovered from the throat, stool, urine, and serum.

Wright and colleagues [256] reported an infant fatality associated with coxsackievirus B1 infection. This premature boy was well until he was 4 days old, when he had two episodes of cyanosis and apnea. He then became anorexic and listless and lost the Moro reflex. On the 9th day of life, he had shallow respirations, hepatomegaly, jaundice, petechiae, and thrombocytopenia. He was edematous and lethargic, and he had a temperature of 34.5° C, a pulse rate of 130 beats/min, and a respiratory rate of 20 breaths/min. He became weaker, unresponsive, and apneic and died. Positive laboratory findings included the following values: platelets, less than 10,000 /mm$^3$; CSF protein, 283 mg/dL; serum bilirubin, 20.5 mg/dL; and serum aspartate aminotransferase, 100 U. Autopsy revealed hepatic necrosis, meningoencephalitis, and myocarditis. Coxsackievirus B1 was recovered from the throat, urine, liver, lung, kidney, and brain.

Twin boys with a sepsis-like illness with hepatitis and disseminated intravascular coagulation have been reported [25]. The first twin died on the 16th day of life, and the second twin survived. Another set of twins had coxsackievirus B1 infections shortly after birth; one twin had myocarditis, and the other had hepatitis with subsequent progressive liver calcifications [382]. A third set of twins had coxsackievirus B1 infections with illness that began when they were 5 days old [453]. One twin had disseminated intravascular coagulation, and the other twin had meningitis. Three other newborns with fatal sepsis-like illnesses with hepatitis have been described [435,441].

Isacsohn and colleagues [232] described four severe cases of neonatal illnesses owing to coxsackievirus B1; three of the four neonates died. One neonate died of myocarditis, and the other two died of multiorgan dysfunction. The surviving infant had hepatitis, congestive heart failure, thrombocytopenia, and residual neurologic damage.

McLean and colleagues [240] described a newborn boy who had a temperature of 39° C, vomiting, and diarrhea on the 4th day of life. When 6 days old, he appeared gray and mottled and developed shallow respirations. He died on the 7th day of life after increased respiratory distress (90 breaths/min), hepatomegaly, generalized edema, and cardiac enlargement. Coxsackievirus B1 was recovered from the heart and brain.

Gear [227] studied an extensive epidemic of Bornholm disease related to coxsackievirus B1 in Johannesburg in summer 1960 through summer 1961. After the first coxsackievirus B1 isolations, the medical officers of the area were on the alert for nursery infections and the prevention of nursery epidemics. Despite careful isolation procedures, Gear [227] reported that infection "was introduced into all the large maternity homes in Johannesburg." About 20 cases of neonatal myocarditis and three deaths were documented. The isolation procedures apparently prevented secondary nursery cases.

Volakova and Jandasek [253] reported epidemic myocarditis related to coxsackievirus B1. Cherry and Jahn [221] described a child with a mild febrile exanthematous illness, which had its onset within 10 minutes of birth.

In 2007, coxsackievirus B1 was the predominant enterovirus in the United States [315]. An increased detection of severe neonatal disease owing to coxsackievirus B1 occurred in association with this predominance. Five fatal cases were noted. Manifestations included myocarditis, meningitis/meningoencephalitis, sepsis-like illness, hepatitis and coagulopathy.

### Coxsackievirus B2

The reported instances of coxsackievirus B2 infections in neonates are listed in Table 24–8. In most instances, the infants had myocarditis or neurologic manifestations. Of the 12 infants with myocarditis, 11 died. The one child with myocarditis who survived was reexamined when 2 years old and was found to be normal [222]. The child's mother became ill with sore throat, coryza, and malaise on the day after delivery. When 3 days old, the child became febrile (38.9° C) and had periods of apnea and cardiac irregularities. The cry was "pained." ECG showed a left-sided heart pattern in the V leads and T wave abnormalities. The infant's symptoms lasted less than 48 hours. Coxsackievirus B2 was isolated from the nose, urine, throat, and CSF of the child and from the mother's stool. The mother breast-fed the infant (while she wore a mask) during her illness. A later specimen of breast milk was cultured for virus without successful recovery of an agent.

Puschak [178] reported a child who became febrile (39.5° C) 8 hours after birth. During the next 9 days, the infant's temperature fluctuated between 36.7° C and 38.9° C. The infant had no other symptoms. Serologic evidence of coxsackievirus B2 infection was found.

Johnson and associates [484] described a 1-month-old infant with aseptic meningitis who developed a persistent right facial paralysis. In a study of undifferentiated diarrheal syndromes, Ramos-Alvarez [452] observed a child with coxsackievirus B2 infection. Eilard and associates [423] reported a nursery outbreak in which 12 infants were infected. All had aseptic meningitis, and two also had myocarditis. One of the two infants died on the 13th day of life. One child with thrombocytopenia and respiratory failure died [427].

### Coxsackievirus B3

Instances of neonatal infections with coxsackievirus B3 are listed in Table 24–8. Most reported cases have been severe illnesses with myocarditis or meningoencephalitis or both. One case involved sudden infant death [379], in which coxsackievirus B3 was recovered from a pool of organs from an infant who died on the 8th day of life.

Tuuteri and coworkers [250] studied a nursery outbreak of coxsackievirus B3 infection. Seven infants had mild disease characterized by anorexia, listlessness, and fever, and two infants had fatal myocarditis. Of the 57 infants with reported neonatal infections with coxsackievirus B3, 30 died; most deaths were associated with myocarditis and sepsis-like illness. Three infants had febrile illnesses with meningitis and were reported to have had no residual effects; long-term follow-up is unavailable, however [175,243].

Isacsohn and colleagues [232] reported two neonates with multiorgan dysfunction who survived. A full-term boy delivered by cesarean section had scattered vesicular lesions at birth [470]. New lesions appeared over a 5-day period, and the rash lasted for 10 days. The infant had no other symptoms, and the mother had no febrile illness during pregnancy.

Chesney and associates [478] studied a 3-week-old girl with meningoencephalitis. This infant had hypoglycorrhachia; the CSF glucose value on the 6th day of illness was 23 mg/dL, with a corresponding blood glucose level of 78 mg/dL. As described in another review [427], two infants who died had thrombocytopenia and respiratory failure; a clinical picture suggestive of necrotizing enterocolitis also was observed.

During a 5-year period in Toronto, Krajden and Middleton [27] assessed 24 neonates with enterovirus infections who were admitted to the Hospital for Sick Children. Nine infants were infected with coxsackievirus B3; of these, two infants had meningitis, three had myocarditis, and four had a sepsis-like illness. Of this group, one infant with meningitis, one with myocarditis, and all with sepsis-like illness died. All the neonates with sepsis-like illness had clinical evidence of multiorgan involvement; they had respiratory distress, hepatomegaly, hemorrhagic manifestations, and congestive heart failure. Two neonates with herpangina and coxsackievirus B3 infections were described in an outbreak involving 25 infants [447]. Fatal myocarditis has been noted in two more recent cases [93,463]. In one case, the infecting virus was found to be a recombinant human enterovirus B variant [93]. The genomic chimera arose from recombination between coxsackievirus B3 and enteroviruses 86 and 87.

### Coxsackievirus B4

Table 24–8 summarizes listings of coxsackievirus B4 neonatal infections. Most were severe and frequently were fatal illnesses with neurologic and cardiac involvement. Sieber and associates [247] described an infant with less severe disease. This infant was well until 6 days after delivery, when he developed pharyngitis, diarrhea, and gradually increasing lethargy; this was followed by fever for 36 hours. No other signs or symptoms were observed, and the infant was well when 11 days old. He had virologic and serologic evidence of coxsackievirus B4 infection.

Winsser and Altieri [254] studied an infant who suddenly became cyanotic and convulsed and died at 2 days of age. At autopsy, the only findings were bronchopneumonia, congestive splenomegaly, and chronic interstitial pancreatitis. Coxsackievirus B4 was isolated from the spleen.

Barson and associates [457] reported the survival of an infant with myocarditis. Cardiac calcification was revealed on radiographs when the infant was 4 weeks old, and ECG revealed a left bundle branch block. When the infant was 7 months old, the conduction defect remained, but the myocardial calcification had resolved.

### Coxsackievirus B5

The spectrum of neonatal infection with coxsackievirus B5 is greater than with the other coxsackievirus B strains. Studies are listed in Table 24–8. Meningitis and

encephalitis are common neonatal manifestations of coxsackievirus B5 infection.* Nursery epidemics have been observed. Rantakallio and associates [244] studied 17 infants with aseptic meningitis in one nursery. None of the infants was severely ill. All had fever, with a temperature of 38° C to 40° C. Eleven of the 17 neonates were boys. Signs included irritability, nuchal rigidity, increased tone, anorexia, opisthotonos, whimpering, loose stools, and diminution of alertness. In another nursery outbreak, Farmer and Patten [419] found 28 infected infants; 15 had aseptic meningitis, 4 had diarrhea, and 9 had no signs of illness. The 15 children who had had meningitis were studied 6 years later; 13 were found to be physically normal and to have normal intelligence. Two children had intelligence levels below the mean for the group and had residual spasticity. At the time of the initial illness, these two infants and one additional child were twitching, irritable, or jittery.

Swender and associates [257] studied seven cases of aseptic meningitis in an intensive care nursery during a 6-week period during the summer of 1972. Two of the infants had apnea. One of the infants had a CSF glucose level of 12 mg/dL. During a community outbreak of coxsackievirus B5 infections, Marier and colleagues [438] studied 32 infants with aseptic meningitis. In this group, 36% had CSF leukocyte counts of 500 cells/mm$^3$ or greater, and neutrophils accounted for 50% or more of the count in 19% of these infants. In 12% of patients, the CSF glucose level was less than 40 mg/dL. Blood leukocyte counts of 15,000 cells/mm$^3$ or greater were detected in 38% of the infants.

Of particular interest is the observation of exanthem in four reports. Cherry and coworkers [477] described a 3-week-old boy with fever, maculopapular rash, and enlarged cervical and postauricular lymph nodes. Examination of the CSF revealed 141 leukocytes/mm$^3$, of which 84% were lymphocytes, and a protein value of 100 mg/dL. ECG was normal. In this infant, the rash appeared before the fever. Coxsackievirus B5 was isolated from the pharynx and the CSF. Nogen and Lepow [243] reported an infant with a similar illness. This infant had a nonspecific erythematous papular rash on the face and scalp. He became febrile and irritable 1 week later. The CSF contained 440 white blood cells/mm$^3$, and 96% of them were mononuclear. Virus was isolated from the feces, throat, and CSF.

Artenstein and associates [219] reported a 23-day-old girl with fever and erythematous macular rash that spread from the scalp to the entire body except the palms and soles and lasted 4 days. Coxsackievirus B5 was recovered from the stool, but no evidence of serum antibody to this virus was found. McLean and coworkers [177] also described an infant with a papular rash on the trunk and limbs that was present at birth. On the 4th day of life, the rash had disappeared, but the patient then developed a temperature of 39.4° C. Irritability, twitching, and fullness of the anterior fontanelle were observed, and CSF examination showed meningitis. During an 8-day period, the infant had repeated episodes of vomiting and diarrhea. On the 11th day of life, the infant had hyperpnea, tachycardia, and an enlarging liver. The infant died on the 13th day of life. Autopsy revealed extensive encephalitis and focal myocardial necrosis. Virus was recovered from the brain, heart, lungs, and liver.

Neonatal infection with coxsackievirus B5 seems less likely to be fatal than infection with other strains of coxsackievirus B. Only 6 of 36 infants presented in Table 24–8 died. In contrast to coxsackieviruses B2, B3, and B4, coxsackievirus B5 seems to be more neurotropic than cardiotropic.

### Echoviruses

#### Echovirus 1

Dömök and Molnár [224] described aseptic meningitis related to echovirus 1.

#### Echovirus 2

Krajden and Middleton [27] described three infants with echovirus 2 infections. Two of the neonates had meningitis and recovered. The third infant, who died, had a sepsis-like illness. Virus was isolated from the CSF, lung, liver, and urine. One other neonate with echovirus 2 infection has been observed, but no details are available [427].

#### Echovirus 3

In summer 1970, Haynes and coworkers [481] studied an epidemic of infection caused by echovirus 3. Three infected neonates were observed, all of whom had meningitis. One child, a full-term girl, developed tonic seizures and an inability to suck on the 3rd day of life. The serum bilirubin level was 28 mg/dL. Shortly thereafter, the infant became cyanotic, flaccid, and apneic and developed a bulging anterior fontanelle; she was in shock. She received assisted ventilation with a respirator for 3 days. When the child was 1 month old, severe neurologic damage with developing hydrocephalus was obvious. Echovirus 3 was recovered from the CSF, and the CSF protein level was 880 mg/dL on the 6th day of life. The other two infants in this study apparently had uncomplicated aseptic meningitis. The CSF findings in one infant revealed 1826 white blood cells/mm$^3$, 91% of which were polymorphonuclear cells. The other infant had 320 cells/mm$^3$, 98% of which were polymorphonuclear cells.

A 4-day-old infant from whom echovirus 3 was recovered from the CSF has been reported [27]. This child had less than 3 white blood cells/mm$^3$ in the CSF. Other neonates with echovirus 3 infection have been observed, but no details are available [201,427].

#### Echovirus 4

Linnemann and colleagues [437] studied 11 infants with echovirus 4 infections. All infants had fevers, and most were irritable. Four infants had a fine maculopapular rash, which was located on the face or abdomen or both. In two infants, the extremities were also involved. Other neonates with echovirus 4 infections have been reported, but details of their illness are unavailable [201,427].

*References 27,167,177,179,238,239,244,249,257,419,438,480.

### Echovirus 5

There have been six reports of neonatal illnesses associated with echovirus 5 infections [360,418,420,470]. In one nursery epidemic, six infants were involved [267]. All infants had fever (38.3° C to 39.7° C) that lasted 4 to 8 days. Two neonates had tachycardia that was disproportionately rapid compared with the degree of fever, but there was no evidence of myocarditis in either infant. Four infants had splenomegaly and enlarged lymph nodes; these findings persisted for several weeks.

In 1966 (July to October), an epidemic of echovirus 5 infection involved 23% of the infants in the maternity unit at the Royal Air Force Hospital in Chargi, Singapore [266]. Of the infants, 56 had symptomatic infection, and 10 had asymptomatic infection. Infants who were ill were 2 to 12 days old at the onset of disease. All 56 symptomatic infants had fever; 87% of them had a temperature of 38.3° C or greater. The mean duration of fever was 3.5 days (range 2 to 7 days). In 20 infants, a faint erythematous macular rash occurred that was most prominent on the limbs and buttocks, but also appeared on the trunk and face. The rash, which began 24 to 36 hours after the beginning of fever, lasted 48 hours. Diarrhea occurred in 17 infants, 4 of whom passed blood and mucus. Vomiting was observed in about half of the neonates. All infants apparently recovered completely.

A newborn girl had a nonspecific, biphasic febrile illness [497]. Echovirus 5 was recovered from the CSF, but the cell count, protein level, and glucose value were normal. Another study included a 9-day-old infant with aseptic meningitis [498]. During an epidemiologic investigation in Rochester, New York, 13 of 75 enterovirus isolates were echovirus 5 [201]. Six of the infants were asymptomatic; no clinical details of the other seven patients were presented. A neonate with sepsis-like illness and hepatic failure died 9 days after birth [364].

### Echovirus 6

Sanders and Cramblett [283] reported a boy who was well until 9 days of age, when he developed a fever (38° C), severe diarrhea, and dehydration. His white blood cell count was 27,900 cells/mm$^3$, and virologic and serologic evidence of echovirus 6 infection was found. Treatment consisted of intravenous hydration, to which there was a good response. Krous and colleagues [363] described an infant who died on the 9th day of life with a sepsis-like illness. The infant had meningitis, disseminated intravascular coagulation, hepatic necrosis, and adrenal and renal hemorrhage. Ventura and associates [388] reported the death of a full-term neonate with sepsis-like syndrome who at postmortem examination had massive hepatic necrosis, adrenal hemorrhagic necrosis, renal medullary hemorrhage, hemorrhagic noninflammatory pneumonia, and severe encephalomalacia.

Yen and coworkers [442,449] reported a premature boy who developed a sepsis-like illness on the 5th day of life. This infant had hepatic failure and was treated with intravenous immunoglobulin. He recovered gradually, but at 62 days of life, he died of a nosocomial *Enterobacter cloacae* infection. Echovirus type 6 has been associated with neonatal illness on two other occasions, but no clinical details are available [427,437].

### Echovirus 7

Piraino and colleagues [383] reported three infants with echovirus 7 infections. All three had fever, one had respiratory distress and exanthem, and one had irritability and loose stools. Two neonates with fatal sepsis-like illnesses with massive disseminated intravascular coagulation have been reported [286,389]. One neonate with severe hepatitis was treated with pleconaril and survived [500]. Daboval and colleagues [467] described an outbreak of echovirus 7 infection in 6 newborns over 12 days. The index case was the mother of one of the infants. The infant of the index case developed fever on the 6th day of life. The subsequent five infants all had illnesses suggestive of sepsis. Five of the infants had macular rashes. All six of the infants had high C-reactive protein levels, but none had evidence of bacterial infection.

### Echovirus 8

In a search for etiologic associations in infantile diarrhea, Ramos-Alvarez [452] identified one neonate from whom echovirus 8 was recovered from the stool. The antibody titer to this virus increased fourfold.

### Echovirus 9

Echovirus 9 is the most prevalent of all the enteroviruses (see Table 24–4). From 1955-1958, epidemic waves of infection spread throughout the world [501]. Since that time, echovirus 9 has been a common cause of human illness. Despite its prevalence and its frequent association with epidemic disease, descriptions of neonatal illness are uncommon. In contrast to experiences with several other enteroviruses, newborn nursery epidemics caused by echovirus 9 have been described rarely.

Neonatal echovirus 9 data are provided in Table 24–9. Moscovici and Maisel [186] described an asymptomatic infant with echovirus 9 infection. When echovirus 9 was

| Krajden and Middleton [27] | Meningitis |

prevalent in Erie County, New York, during the summer of 1971, seven neonatal cases were observed [451]. Four children had aseptic meningitis, but only moderate elevations of CSF protein values and white blood cells were observed. A 15-day-old infant had radiologic evidence of bronchopneumonia, and two infants had gastroenteritis. Rawls and coworkers [387] described an infant who was well until the 7th day of life, when progressive lethargy, anorexia, and irritability developed. The child became moribund, and jaundice, scattered petechiae, and hypothermia were observed. The pulse rate was 90 beats/min, the respiratory rate was 40 breaths/min, and the liver was enlarged. The infant died 3 days after the onset of symptoms. Echovirus 9 was recovered from the lung, brain, and CSF. Cho and colleagues [433] described a similar severe neonatal illness in an infant boy from whom echovirus 9 was recovered from the CSF. This infant was hypothermic and hypotonic on the 3rd day of life. He had bilateral pneumonia and leukopenia. After a stormy course, which included an exchange transfusion for suspected sepsis and mechanical ventilation for apnea, he eventually recovered.

Jahn and Cherry [234] described an infant who became febrile (38.3° C), irritable, and anorectic on the 6th day of life. This infant became asymptomatic within 2 days; echovirus 9 was recovered from the throat, feces, serum, and CSF. Eichenwald and Kostevalov [187] reported two children with mild irritability, fever, and diarrhea and a third child with diarrhea and convulsions in whom laboratory findings showed aseptic meningitis. Haynes and colleagues [482] studied a large outbreak of meningoencephalitis caused by echovirus 9 and described nine infants who were 2 weeks to 2 months old. Cheeseman and associates [390] studied a neonate with fatal interstitial pneumonia, and Krajden and Middleton [27] reported a 4-day-old infant from whom echovirus 9 was recovered from the CSF. This infant had less than 3 white blood cells/$mm^3$ in the CSF.

## Echovirus 11

Neonatal illness associated with echovirus 11 infection has been varied. Reported cases are listed in Table 24–10. Eleven of the reports involved nursery outbreaks; in five reports, the neonatal cases were part of a larger community epidemic. Miller and associates [276] studied an epidemic of aseptic meningitis and other acute febrile illnesses in New Haven, Connecticut, in summer 1965. This epidemic was unique in that half of the patients with meningitis from whom virus was isolated were younger than 6 months. The echovirus 11 in this epidemic was a prime strain. Three neonatal illnesses were reported. One of the patients, a 1-month-old infant, was initially irritable and feverish and had diarrhea. Chest radiographs revealed bilateral pneumonitis. A generalized, discrete maculopapular rash, which lasted 24 hours, was seen on the 3rd day of illness. Fever persisted for 6 days. A 12-day-old girl had fever (39.4° C) lasting 1 day, but no other findings. Echovirus 11 was recovered from her throat. Another 1-month-old infant had aseptic meningitis.

Sanders and Cramblett [283] described two infants with diarrhea. Both infants were acutely ill; one was jaundiced and irritable and had feeding difficulty. In another study, two infants with echovirus 11 infections had diarrhea [258]. One infant had a temperature of 39.3° C and a "stuffy nose," and the other had a temperature of 39.8° C and aseptic meningitis. Cramblett and coworkers [261] observed an outbreak of nosocomial infections caused by echovirus 11 in a neonatal intensive care unit. In a 1-month-old premature infant with frequent apneic episodes, the CSF contained 2200 white blood cells/mm$^3$, 89% of which were polymorphonuclear cells, and the protein level was 280 mg/dL. The infant made a gradual recovery. Echovirus 11 was isolated from the CSF and stool. In another premature infant, apneic episodes and bradycardia suddenly began on the 20th day of life. Fever developed, the apneic spells continued, and digitalis therapy was necessary because of congestive heart failure. Examination of the CSF revealed aseptic meningitis, and echovirus 11 was recovered from the CSF, throat, and stool. A third child with aseptic meningitis had an exanthem. The disease began suddenly, and the child had shallow respirations and poor skin color. On the next day, generalized seizures occurred, and a maculopapular rash developed on the trunk, extremities, and face. The child made a gradual recovery. A fourth child had a severe, nonspecific febrile illness.

A particularly noteworthy finding in neonatal echovirus 11 infection has been severe sepsis-like illness with hepatitis or hepatic necrosis, disseminated intravascular coagulation, and extensive hemorrhagic manifestations.*

*References 195,262,277,279,357–363,382,387.

During the past 15 years, more than 40 such cases have been described, and most of the illnesses have been fatal.

Hercík and coworkers [269] reported an epidemic of respiratory illness in 22 newborns. Six of the infants were severely ill, and one subsequently died. The incubation period varied from 17 hours to 9 days (average 3 days). Seven infants had interstitial pneumonia, and all had rhinitis, pharyngitis, and vomiting. Toce and Keenan [502] reported two newborns with respiratory distress and pneumonia at birth. Both infants died of echovirus 11 infection. Tarcan and colleagues [503] described a 5-day-old boy who developed fever and diarrhea. He developed a maculopapular rash on the face, generalized petechiae and hemorrhagic bullae, and pancytopenia owing to bone marrow failure. This infant was treated with intravenous immunoglobulin and recovered.

An outbreak of echovirus 11 infections in neonates in a confinement home in Penaug, Malaysia, was noted in September and October 2004 [422]. Of the two primary cases from a hospital nursery, one went to the confinement home and became symptomatic there. Of the 13 infants in the confinement home, 11 developed febrile illnesses. In addition, five infants had diarrhea, three infants had coryza, two infants had difficulty breathing, and one infant had jaundice.

An infant in a neonatal unit in London, England, developed lethargy and fed poorly 3 days after birth [440]. The neonate had temperature fluctuations and recurrent hypoglycemia and aseptic meningitis. The mother of the infant had pleurodynia at the time of delivery. An echovirus 11 outbreak occurred in a nursery in Taipei, Taiwan, in November 2003 [504]. Symptomatic illness developed in 12 neonates; 3 infants had asymptomatic infection. One infant developed respiratory failure, hypotonia, disseminated intravascular coagulopathy, and bacterial grade IV intraventricular hemorrhage and died at a referral center from extensive pulmonary hemorrhage 6 days after admission. A second infant had fulminant hepatitis, anemia, aseptic meningitis, and disseminated intravascular coagulopathy, but survived after a lengthy hospital stay. The other 10 infants who were referred because of fever all recovered without sequelae. The source of infection in the index patient was the mother.

### Echovirus 13

Before 2000, infection with echovirus 13 was rare in neonates. The virus was isolated from one asymptomatic infant in a neonatal surveillance study [201]. In 2001 in the United States, echovirus 13 was the leading cause of aseptic meningitis, and during 2001-2002, aseptic meningitis outbreaks with this agent occurred in many countries [366,480,483,505]. Many cases were infants who were 3 months or younger [506]. A 28-day-old boy in Tennessee had aseptic meningitis and hepatitis [507]. Neonatal cases were reported in Israel and Spain, but details were not presented [508,509].

### Echovirus 14

Hughes and colleagues [189] reported an infant boy who became febrile (38° C) and had cyanotic episodes on the 3rd day of life. When 4 days old, his temperature was 38.9° C, and he experienced recurrent apneic spells. Liver enlargement, hypothermia, bradycardia, periodic breathing, and spontaneous ecchymoses developed, and the infant died on the 7th day of life. Laboratory studies revealed the presence of leukopenia and thrombocytopenia, and autopsy showed severe hepatic necrosis. Drouhet [510] described a child with aseptic meningitis and echovirus 14 infection, and Hinuma and associates [511] reported four newborns with apparent asymptomatic echovirus 14 infections.

### Echovirus 16

In 1974, Hall and colleagues [436] studied five neonates with echovirus 16 infections. All five infants were admitted to the hospital because sepsis was suspected. Four of five were febrile, all were lethargic and irritable, and two had abdominal distention. Three of the neonates had erythematous maculopapular exanthems, and in two, the rash appeared after or with defervescence. Leukocyte counts in four infants revealed an increased percentage of band form neutrophils. Two neonates had aseptic meningitis. Lake and associates [427] observed three infants with echovirus 16 infections. In their study, clinical findings were not itemized by virus type, but it is inferred that sepsis-like illnesses occurred.

### Echovirus 17

Neonatal infection with echovirus 17 has been observed by three investigators. Cherry and coworkers [174] reported two ill infants. A 19-day-old infant developed otitis media 5 days after his mother had a flulike illness. Echovirus 17 was isolated from his feces, and serologic evidence of echovirus 17 infection was found in the infant and the mother. The second infant had a nonspecific febrile illness at the age of 4 weeks, which was severe enough to require hospitalization. Virus was isolated from the infant's throat, feces, and serum.

Sanders and Cramblett [283] described two neonates with exanthem associated with echovirus 17. The first infant, a 3-week-old girl, became drowsy, anorectic, and febrile. She had a fine maculopapular rash on the trunk, a slightly injected pharynx, and a few petechiae on the soft palate. She remained febrile for 5 days. Echovirus 17 was recovered from the CSF and the feces. The second infant became ill at 3 weeks of age. His symptoms were mild rhinitis and cough followed by lethargy and refusal to eat. His temperature was 39° C 4 days after the onset of symptoms, and his respiratory rate was 60 breaths/min. A fine maculopapular rash appeared on the trunk, and radiographs revealed an infiltrate in the right lung. The infant's course was uneventful, and he was much improved 12 days after the onset of symptoms.

Faulkner and van Rooyen [265] described an outbreak of echovirus 17 infection with illness in a nursery in mid-August 1971. Seven infants were involved, including one with aseptic meningitis who was 7 weeks old. All the infants had fever, four had CNS signs, three had abdominal distention, four had diarrhea, and three had a rash. One other infant from another community was also studied by the investigators. This infant had febrile pneumonitis when 3.5 weeks old. The findings abated in 5 days,

but the infant suddenly died 6 days later. Autopsy revealed interstitial pneumonitis with extensive edema and scattered petechial hemorrhages of the viscera. Echovirus 17 was isolated from the liver, lung, spleen, and kidney.

### Echovirus 18

In 1958, Eichenwald and colleagues [263] described epidemic diarrhea associated with echovirus 18 infections. In a nursery unit of premature infants, 12 of 21 infants were mildly ill. Neither temperature elevation nor hypothermia occurred. Six infants were lethargic and listless, and two developed moderate abdominal distention. The diarrhea lasted 1 to 5 days; there were five or six watery, greenish stools per day, occasionally expelled explosively. In two infants, a small amount of blood was seen in the stools, but there was no mucus or pus cells. Five other infants in another nursery had similar diarrheal illness. Echovirus 18 was recovered from all ill infants.

Medearis and Kramer [512] reported a 3-week-old girl with fever, irritability, lethargy, pharyngitis, and postnasal drainage. She was admitted to the hospital because of apneic spells and developed a generalized erythematous blotchy macular rash and had frequent stools. The illness lasted about 7 days. Echovirus 18 was recovered from the blood, throat, and feces. Berkovich and Kibrick [258] found echovirus 18 in the stool of a 12-day-old twin infant with fever and a red throat. The relationship of echovirus 18 to the illness is uncertain because the patient's twin was infected with echovirus 11, and the patient also had serologic evidence of echovirus 11 infection. The fever and red throat may have been caused by echovirus 11, rather than echovirus 18 infection. Wilfert and associates [505] observed a 9-day-old infant with aseptic meningitis.

Kusuhara and coworkers [469] described an outbreak of echovirus 18 infection in a neonatal intensive care unit involving 20 patients. This outbreak occurred between November 3 and November 24, 2003, and involved patients 1 week to 6 months old. Of the infants, 8 had acute exanthematous diseases, 1 had transient fever, and the other 11 were asymptomatic.

### Echovirus 19

Cramblett and coworkers [465] described two neonates with echovirus 19 infections. One infant had an upper respiratory infection, cough, and paroxysmal atrial tachycardia. The other infant also had an upper respiratory infection, but in addition to echovirus 19 infection, coxsackievirus B4 was recovered from the throat of this infant. Butterfield and associates [260] isolated echovirus 19 post mortem from the brain, lung, heart, liver, spleen, lymph nodes, and intestine of a premature infant who had cystic emphysema. The relationship between the generalized viral infection and the pulmonary disease is not understood.

Philip and Larson [386] reported three catastrophic neonatal echovirus 19 infections, which resulted in hepatic necrosis and massive terminal hemorrhage. One infant, infected in utero, was symptomatic at birth. The Apgar score was 3, and multiple petechiae were observed. The infant had generalized ecchymoses and apneic episodes and died when 3.5 hours old. Thrombocytopenia was identified, and echovirus 19 was isolated from the brain, liver, spleen, and lymph nodes. The other two infants who died of echovirus 19 infection were twins. They were normal during the first 3 days of life, but then became mildly cyanotic and lethargic. Shortly thereafter, apneic episodes occurred, and jaundice and petechiae developed. Both twins became oliguric, and they died on the 8th and 9th days of life, with severe gastrointestinal bleeding. Both twins were thrombocytopenic, and virus was recovered from systemic sites in both. Two similar catastrophic cases have been described [493].

Purdham and associates [281] reported an outbreak of echovirus 19 in a neonatal unit in which 12 infants were affected; 11 infants were febrile, 10 were irritable, 7 had marked abdominal distention with decreased bowel sounds, and 5 had apneic episodes. Bacon and Sims [428] described two neonates with sepsis-like illness. The infants were cyanotic with peripheral circulatory failure. In another study involving the same echovirus 19 epidemic, five infants younger than 3 months were reported [434]. All had sepsis-like illness with hypotonia and peripheral circulatory failure. Two infants had aseptic meningitis, and two others had diarrhea.

### Echovirus 20

Eichenwald and Kostevalov [187] recovered echovirus 20 from four asymptomatic infants younger than 8 days (see "Cloud Baby"). Five neonates with severe illness owing to echovirus 20 have also been described [384,443]. All had hepatitis, and two died.

### Echovirus 21

Jack and coworkers [270] recovered echovirus 21 from the feces of a 7-day-old infant with jaundice and diarrhea. No other details of the infant's illness are available. Chonmaitree and associates [459] studied a 19-day-old infant with aseptic meningitis and rash, and Georgieff and colleagues [385] reported a newborn with fulminant hepatitis. Lake and colleagues [427] also mentioned one infected infant, but presented no specific details.

### Echovirus 25

Linnemann and colleagues [437] reported one neonate with echovirus 25 infection. They gave no virus-specific details except that fever and irritability occurred.

### Echovirus 30

Matsumoto and associates [485] described a nursery outbreak involving 11 infants during a 2-week period. All the neonates had aseptic meningitis, and all recovered. Two symptomatic and six asymptomatic neonates were reported in the Rochester, New York, surveillance study [201]. Chen and associates [431] described twin neonates who had fever followed by thrombocytopenia, coagulopathy, and hepatic failure. One of the neonates died, and the other survived and had no obvious sequelae at 1 year of age. In another study, twins had a sepsis-like illness with hepatitis [439]. These twins survived and had normal development and normal liver function at 1 year of age.

### Echovirus 31

McDonald and associates [274] described three neonates in an intensive care nursery with echovirus 31 infections. One infant had a fatal encephalitis-like illness, with hypertonicity, hyperreflexia, and apneic spells. The other two infants also experienced apneic spells, and one also had pneumonia and meningitis.

### Echovirus 33

In a study of epidemic illness related to echovirus 33 disease in the Netherlands, Kapsenberg [271] stated that 7- to 8-day-old neonates in a maternity ward had a febrile illness. No further data were presented.

## *Enterovirus 71*

Schmidt and colleagues [366] mentioned one 3-week-old infant with meningitis and enterovirus 71 infection. Chonmaitree and colleagues [450] described one 9-day-old neonate with aseptic meningitis and one 14-day-old infant with gastroenteritis from enterovirus 71. Chen and associates [471] reported a child with bilateral lower limbs weakness in association with the hand-foot-and-mouth syndrome.

## *Parechoviruses*

### Parechovirus 1

Parechovirus 1 has been associated with three epidemics of nursery infections. During a survey of perinatal virus infections by Jack and coworkers [270], 44 infants were found to be infected with parechovirus 1 during a study period from May to December 1966. The virus prevalence and the incidence of new infections during this period were fairly uniform. No illness was attributed to parechovirus 1 infection, and the virus disappeared from the nursery in mid-December 1966. Berkovich and Pangan [259] studied respiratory illnesses in premature infants and reported 64 infants with illness, 18 of whom had virologic or serologic evidence of parechovirus 1 infection. Many other infants had high but constant levels of serum antibody to parechovirus 1. Some of these infants were probably also infected with parechovirus 1. The children with proven parechovirus 1 infections could not be clinically differentiated from children without evidence of parechovirus 1 infection.

Of 18 infants with documented parechovirus 1 infections, 90% had coryza, 39% had pneumonia, and 11% had morbilliform rash or conjunctivitis or both. In contrast to the studies of Jack and coworkers [270], only 3 of 35 asymptomatic infants were found to be infected with parechovirus 1. Nakao and associates [280] recovered parechovirus 1 from 29 premature infants. Many of the infected infants were asymptomatic, and infants who were ill had only mild symptoms of coryza, cough, and diarrhea. Jenista and colleagues [201] described 17 parechovirus 1 infections in nonhospitalized neonates. Clinical details were not presented, but it seems that all of these infants were asymptomatic. Parechovirus 1 infection was associated with a nosocomial necrotizing enterocolitis outbreak [456].

In a study in Dutch children, Benschop and colleagues [429] compared the clinical findings in 27 children with parechovirus 1 with 10 children with parechovirus 3. They identified only the median ages of the children, so we do not know the number of neonates with illnesses. The investigators found that sepsis-like illness and CNS symptoms were more common in the parechovirus 3 cases compared with parechovirus 1 cases.

### Parechovirus 2

Ehrnst and Eriksson [479] reported a 1-month-old girl with encephalopathy resulting from a nosocomial parechovirus 2 infection. No further details of this case were provided.

### Parechovirus 3

Many more recent studies of illness with parechovirus 3 infections in neonates and young infants have been presented [34,35,429,430,491]. Four of five studies occurred in the Netherlands. In one study of 10 neonates and young infants, 90% had fever, 70% had sepsis-like illness, 70% had gastrointestinal tract symptoms, 50% had CNS symptoms, and 30% had respiratory tract symptoms [429]. In a subsequent study of 29 young children (median age 1.2 months) by members of the same group, the following findings were noted: fever 97%, irritability 86%, sepsis-like illness 75%, meningitis 12%, seizures 7%, encephalitis 4%, paralysis 4%, rash 17%, gastrointestinal tract symptoms 39%, and respiratory tract symptoms 36%.

Boivin and associates [430] in Quebec, Canada, reported three neonates with high fever, erythematous rash, and tachypnea. Verboon-Maciolak and coworkers [34] compared neonatal illness with parechovirus 3 with illness owing to enteroviruses; the only differences noted were that gastrointestinal tract symptoms were more common in the parechovirus 3 group, and C-reactive protein and CSF protein were higher in the enterovirus group [491]. Members of the same group carefully studied encephalitis in 10 neonates. All had white matter injury. Six of the 10 neonates were normal on later follow-up. One child had cerebral palsy with epilepsy, one child had learning disabilities, one child had epilepsy but normal cognitive outcome at 3 years of age, and one child had mild distal hypertonia at 18 months of age.

### Parechovirus 4

A neonate with fever and poor feeding was found to be infected with parechovirus 4 [424].

# DIAGNOSIS AND DIFFERENTIAL DIAGNOSIS

## CLINICAL DIAGNOSIS

The clinical differentiation of neonatal infectious diseases frequently seems to be an impossible task. Although treatable bacterial and viral illnesses should always be considered and treated first, when all the circumstances of a particular neonatal illness are considered, enterovirus and parechovirus diseases can be suspected on clinical grounds. The most important factors in clinical diagnosis

are season of the year, geographic location, exposure, incubation period, and clinical symptoms.

In temperate climates, enterovirus and parechovirus prevalence is distinctly seasonal, and disease is usually seen in the summer and fall. Neonatal enterovirus disease is unlikely in the winter. In the tropics, enteroviruses are prevalent throughout the year, and the season is not helpful diagnostically.

As with all infectious illnesses, knowledge of exposure and incubation time is important. A careful history of maternal illness is vital, particularly the symptoms of maternal illness. Nonspecific mild febrile illness in the mother that occurs in the summer and fall should warn of the possibility of more severe neonatal illness. More specific findings in the mother (e.g., aseptic meningitis, pleurodynia, herpangina, pericarditis, myocarditis) should alert the clinician to look for more specific enterovirus illnesses. Minor illness in nursery personnel during enterovirus seasons and the short incubation period of enterovirus and parechovirus infections should be taken into consideration. Manifestations of neonatal nonpolio enterovirus and parechovirus infections are listed in Table 24–5.

## LABORATORY DIAGNOSIS

### Virus Isolation

Most viral diagnostic laboratories have facilities for the recovery of most enteroviruses and parechoviruses that cause congenital and neonatal illness. Three tissue culture systems—primary rhesus, cynomolgus, or African green monkey kidney tissue culture; a diploid, human embryonic lung fibroblast cell strain; and the RD cell line—allow the isolation of all polioviruses, coxsackievirus B strains, echoviruses, newer enteroviruses, parechoviruses, and many coxsackievirus A strains. In a 1988 study in which Buffalo green monkey kidney cells and subpassages of primary human embryonic kidney cells were used in addition to primary monkey kidney and human diploid fibroblast (MRC-5) cells, the enterovirus recovery rate was increased by 11% [513]. For a complete diagnostic isolation spectrum, suckling mouse inoculation should also be performed. Optimally, at least one blind passage should be done in each of the culture systems.

Proper selection and handling of specimens are most important in the isolation of viruses from ill neonates. Because infection in neonates tends to be generalized, collection of material from multiple sites is important. Specimens should be taken from any or all of the following: nasopharynx, throat, stool, blood, urine, CSF, and any other body fluids that are available. Swabs from the nose, throat, and rectum should be placed in a transport medium.

Transport medium provides a protective protein, neutral pH, and antibiotics for control of microbial contamination and, most importantly, prevents desiccation. Many viral transport and storage media are commercially available or are prepared readily in the laboratory; their utility has been reviewed elsewhere [514]. Convenient and practical collection devices, such as the Culturette (Becton-Dickinson, Cockeysville, MD) or Virocult (Medical Wire and Equipment Co, Victory Gardens, NY), consist of a swab, usually Dacron or rayon, on a plastic or aluminum shaft accompanied by a self-contained transport medium (Stuart or Amies) and are routinely available in most hospitals for bacteriologic culture. Calcium alginate swabs, which are toxic to herpes simplex virus, and wooden shafts, which may be toxic for viruses and the cell culture system itself, should not be used. Saline or holding media that contain serum also should be avoided. Useful liquid transport media (2-mL aliquots in screw-capped vials) consist of tryptase phosphate broth with 0.5% bovine albumin; Hanks balanced salt solution with 5% gelatin or 10% bovine albumin; or buffered sucrose phosphate (0.2M, 2-SP) [514,515], which has been used as a combined transport for viral, chlamydial, and mycoplasmal culture requests and is appropriate for long-term frozen storage of specimens and isolates [516].

Fluid specimens should be collected in sterile vials. Specimens of autopsy material are best collected in vials that contain transport medium. Generally, specimens should be refrigerated immediately after collection and during transportation to the laboratory. Specimens should not be exposed to sunlight during transportation. If an extended period is likely to elapse before a specimen can be processed in the laboratory, it is advisable to ship and store it frozen.

Evidence of enterovirus growth from tissue cultures takes only a few days in many cases and less than 1 week in most [109]. The use of the spin amplification, shell vial technique, and monoclonal antibodies has significantly reduced the time for detection of enterovirus cultures [55,517]. After isolation of an enterovirus, identification of its type is conventionally done by neutralization, which is an expensive and lengthy process.

### Rapid Virus Identification

Because of the many different serotypes of enteroviruses and parechoviruses, immunofluorescence, agglutination, counterimmunoelectrophoresis, and ELISA techniques for the direct detection of antigen in suspected enterovirus infections have not been useful. Nucleic acid techniques with cDNA and RNA probes have been useful for the direct identification of enteroviruses [74,496,507–509]. The development of numerous PCR techniques has been most important. Since 1990, innumerable reports have described enterovirus and more recently parechovirus PCR methods and their use in identifying enterovirus and parechovirus RNA in clinical specimens.* PCR has proved most useful for the direct identification of enteroviruses and parechoviruses in the CSF of patients with meningitis. Compared with culture of CSF specimens, PCR is more rapid and sensitive, and the specificity is equal.

PCR also has proved useful in the identification of enteroviruses in blood, urine, and throat specimens.† Particularly impressive are the findings of Byington and associates [19]. Using PCR on specimens of blood and CSF, these investigators found that more than 25% of

*References 51–53,55–58,61–67,109,501,510,513–518.

†References 19,51,58,64,513,514,519.

infants admitted to the hospital for suspected sepsis in 1997 had nonpolio enterovirus infections. Based on this study and a subsequent study in Utah and the work of Adréoletti and coworkers and others [52,520], the general work-up for febrile neonates hospitalized for possible sepsis should include PCR for enteroviruses in blood and CSF. This is most important during enterovirus and parechovirus season (summer and fall in temperate climates), but because enterovirus circulation continues all year, it is reasonable to perform PCR in the off seasons. Although PCR detects enterovirus RNA, the specific enterovirus type is not identified. Because of this shortcoming, conventional culture should be performed along with PCR.

PCR has also identified enteroviruses in frozen and formalin-fixed biopsy and autopsy specimens of myocardium [51,58,64,513,514]. In one study, enteroviruses were identified in myocardial tissue from four neonates who died of myocarditis [521]. In one case, the specimen was obtained during life by a right ventricular endomyocardial biopsy, and in the other three, frozen or formalin-fixed autopsy samples were used. Most PCR methods can detect one tissue culture infective dose of enterovirus in CSF, stool, or throat specimen [522]. Polioviruses can be separated from other enteroviruses, and poliovirus vaccine strains can be rapidly identified by PCR [109,492,515–518,523].

Enterovirus RNA has been identified in numerous tissue specimens from patients with chronic medical conditions, such as idiopathic dilated cardiomyopathy. The possibility of lack of specificity (false-positive results) is a concern, however.

### Serology

Except in special circumstances, the use of serologic techniques in the primary diagnosis of suspected neonatal enterovirus infections is impractical. Standard serologic study depends on the demonstration of an increase in antibody titer in response to a specific virus as an indication of infection with that agent. Although hemagglutination inhibition, ELISA, and complement fixation tests take only a short time to perform, these tests can be done only after the collection of a second, convalescent-phase blood specimen. These tests are also impractical in searching for the cause of a specific illness in a child because there are so many antigenically different enteroviruses. As discussed in "Antigenic Characteristics," group antigens can be produced that allow serologic diagnosis by IgM enzyme immunoassay and complement fixation, but these tests lack specificity [110,111,524].

In the evaluation of an infant with a suspected enterovirus infection, serum should be collected as soon as possible after the onset of illness and again 2 to 4 weeks later. This serum should be stored frozen. In most clinical situations, it is unnecessary to perform serologic tests on the collected serum because demonstration of an antibody titer increase in the serum of an infant from whom a specific virus has been isolated from a body fluid is superfluous. Collected serum can be useful diagnostically, however, if the prevalence of specific enteroviruses or parechoviruses in a community is known. In this situation, it is easy to look for antibody titer changes to a selected number of viral types. More rapid diagnosis using a single serum sample is possible if a search for specific IgM enterovirus antibody is made [247,519,521,522,525–530].

Enterovirus IgM antibody tests are not commercially available. Commercial laboratories offer enterovirus complement fixation antibody panels. These tests are expensive, however, and their results in the clinical setting are almost always meaningless unless acute phase and convalescent phase sera are analyzed.

### Histology

There are no specific histologic findings in enterovirus infections, such as seen in cytomegalovirus or herpes simplex virus infections. Tissues can be examined, however, for specific enterovirus antigens by immunofluorescent study and by PCR [179,501,531,532].

## DIFFERENTIAL DIAGNOSIS

The differential diagnosis of congenital and neonatal enterovirus infections depends on the clinical manifestations. Generally, the most important illness categories are generalized bacterial sepsis or meningitis, congenital heart disease, and congenital and neonatal infections with other viruses.

Hypothermia and hyperthermia associated with nonspecific signs, such as lethargy and poor appetite, are common in neonatal enterovirus infections; they are also the presenting manifestations in bacterial sepsis. Proper bacterial cultures are essential. Differentiation between congenital heart disease and neonatal myocarditis is frequently difficult. The occurrence of fever or hypothermia, generalized lethargy and weakness, and characteristic ECG changes should suggest a viral cause.

Congenital infections with rubella virus, cytomegalovirus, *Toxoplasma gondii*, or *Treponema pallidum* are frequently associated with intrauterine growth restriction; this is not usual with enterovirus infections. Generalized herpes simplex virus infections are clinically similar to severe infections with several enteroviruses; in herpes infections, skin lesions are common, and a scraping of a lesion and a culture should allow a rapid diagnosis. In infants with signs of CNS involvement, it is particularly important to consider herpes simplex virus infection as a possible cause because infection with this agent is treatable, and early treatment is essential. In infants with meningitis, proper cultures and PCR testing are essential because the CSF findings in bacterial and viral illnesses are frequently similar.

# PROGNOSIS

## POLIOVIRUSES

As substantiated in the review by Bates [127] and the summary in Table 24–7, poliovirus infections in neonates are generally severe. Of the 44 cases with available follow-up data, there were 21 deaths; of the survivors, 12 had residual paralyses. Because infant survivors of poliomyelitis are susceptible to infection by the other two types of poliovirus, they should receive polio vaccine.

## NONPOLIO ENTEROVIRUSES AND PARECHOVIRUSES

The immediate prognosis for patients with coxsackievirus and echovirus infections is related to the specific manifestations. Mortality rates are highest for infants with myocarditis, encephalitis, or sepsis-like illness with liver involvement. Differences in the severity of illness depend on viral type and strain variations. Generally, infections with coxsackieviruses B1 to B4 and with echovirus 11 seem to carry the most ominous initial prognoses. Also of concern are CNS infections with parechovirus 3.

Information related to long-term sequelae of neonatal coxsackievirus and echovirus infections is sparse. In a 4-year follow-up study, Gear [229] found no evidence of permanent cardiac damage in several children who had coxsackievirus B myocarditis. For children with aseptic meningitis, there is little available evidence of neurologic damage. One of five infants studied by Nogen and Lepow [243] from whom virus was recovered from the CSF was suspected to have brain damage. Cho and colleagues [433] reported that a child who had had severe neonatal echovirus 9 disease was developing normally at 1 year of age. Tuuteri and associates [250] reported that two children who had had clinically mild neonatal coxsackievirus B3 infections were thriving when seen at 1 year of age. After an epidemic of mild febrile disease related to echovirus 5, 51 children were examined at 1 year of age and found to be normal [266].

Farmer and colleagues [480] did a careful follow-up study of 15 children who had meningoencephalitis related to coxsackievirus B5 during the neonatal period. When 6 years old, two of the children were found to have developed spasticity, and their intelligence was below the mean for the study group as a whole and below the mean of a carefully selected control group. Three children who had myocarditis and meningoencephalitis had no cardiac sequelae at the age of 6 years. Sells and associates [487] described neurologic impairment at later follow-up of some children who had CNS enterovirus infections during the 1st year of life.

In a study in which nine children with enterovirus meningitis during the first 3 months of life were compared with nine matched control children, Wilfert and associates [498] found that the receptive language functioning of patients was significantly less than that of the controls. Head circumference, hearing, and intellectual function were similar for patients and controls. Bergman and colleagues [473] reported an extensive study in which 33 survivors of enterovirus meningitis during infancy were compared with their siblings. In this comprehensive study, none of the survivors had major neurologic sequelae, and they performed as well as their siblings on numerous cognitive, achievement, perceptual motor skills, and language tests. Rantakallio and coworkers [461] found that 16 of 17 patients with neonatal meningitis related to coxsackievirus B5 had normal neurologic development on follow-up. The one exception was a child with suspected intrauterine myocarditis. In another study, 16 newborns with meningitis related to coxsackievirus A14 were normal 2.5 years later.

The most alarming report is that of Eichenwald [533], who gave details of a 5-year follow-up study of infants who had had neonatal diarrhea associated with echovirus 18 infection [263]. Thirteen of 16 infants who had had an echovirus 18 infection during the neonatal period showed neurologic damage; these children had an IQ of less than 70, spasticity, deafness, blindness, or a combination of these effects.

In most instances, the antibody response of neonates after enterovirus infection is good. It is to be expected that one attack of infection with a particular viral type provides immunity to the specific agent in the future. From the evidence derived from polio vaccine studies, it is probable that reinfection with all enteroviruses is common, but that after an initial antibody response, a secondary inapparent infection occurs and is confined to the gastrointestinal tract.

# THERAPY

## SPECIFIC THERAPY

No specific therapy for any enterovirus infection is approved for use in the United States. In severe, catastrophic, and generalized neonatal infection, it is likely that the infant received no specific antibody for the particular virus from the mother. In this situation, it is probably advisable to administer human immune serum globulin to the infant. Dagan and associates [534] examined three lots of human serum globulin and found the presence of neutralizing antibodies to several commonly circulating and infrequently circulating enteroviruses. Although there is no evidence that this therapy is beneficial in treating acute neonatal infections, there is evidence of some success in the treatment of chronic enterovirus infections in agammaglobulinemic patients [535]. Because it was found by Hammond and coworkers [536] that a single dose of intramuscular immunoglobulin resulted in little change in circulating neutralizing antibodies to coxsackievirus B4 and echovirus 11 in seven infants, it seems advisable when therapy is decided on to use high-dose intravenous immunoglobulin. One neonate with disseminated echovirus 11 infection with hepatitis, pneumonitis, meningitis, disseminated intravascular coagulation, decreased renal function, and anemia survived after receiving a large dose of intravenous immunoglobulin and supportive care [537].

Abzug and colleagues [538] performed a small controlled study in which nine enterovirus-infected neonates received intravenous immunoglobulin, and seven similarly infected infants received supportive care. In this study, there was no significant difference in clinical scores, antibody values, or magnitude of viremia and viruria in infants treated compared with the control infants. Five infants received intravenous immunoglobulin with a high neutralizing antibody titer (≥1:800) to their individual viral isolates, however, and they had a more rapid cessation of viremia and viruria.

Jantausch and associates [539] reported an infant with a disseminated echovirus 11 infection who survived after maternal plasma transfusions. The role, if any, of these

transfusions in the infant's recovery is unknown, and this form of therapy cannot be recommended. A neonate with fulminant hepatitis caused by echovirus 11 infection survived after orthotopic liver transplantation [540].

Many antipicornavirus drugs and biologicals have been studied during the past 30 years [68,69]. The antiviral drug pleconaril offers promise for the treatment of enterovirus infections.* This drug is a novel compound that integrates into the capsid of enteroviruses. It prevents the virus from attaching to cellular receptors and prevents uncoating and subsequent release of viral RNA into the host cell. In a double-blinded, placebo-controlled study of 39 patients with enterovirus meningitis, a statistically significant shortening of the disease duration was noted from 9.5 days in controls to 4 days in drug recipients [68]. Pleconaril also has been used on a compassionate-release basis in the treatment of patients with life-threatening infection [542]. Several categories of enterovirus illnesses have been treated: chronic meningoencephalitis in patients with agammaglobulinemia or hypogammaglobulinemia, neonatal sepsis, myocarditis, poliomyelitis (wild-type or vaccine associated), encephalitis, and bone marrow transplant patients. Favorable clinical responses were observed in 22 of 36 treated patients, including 12 of 18 patients with chronic meningoencephalitis. In the absence of controls, the extent to which the favorable outcomes can be attributed to pleconaril is unknown. At the present time, pleconaril is unavailable in the United States.

In severe illnesses, such as neonatal myocarditis or encephalitis, it is frequently tempting to administer corticosteroids. Although some investigators thought this approach was beneficial in treating coxsackievirus myocarditis, we believe that corticosteroids should not be given during acute enterovirus infections. The deleterious effects of these agents in coxsackievirus infections of mice [543] are particularly persuasive. Immunosuppressive therapy for myocarditis of unknown origin with prednisone and cyclosporine or azathioprine was evaluated in a controlled trial of 111 adults, and no beneficial effect was observed [544].

Because the possibility of bacterial sepsis cannot be ruled out in most instances of neonatal enterovirus infections, antibiotics should be administered for the most likely potential pathogens. Care in antibiotic selection and administration is urged so that drug toxicity is not added to the problems of the patient. In neonates with meningitis or meningoencephalitis and in some infants with sepsis-like illnesses, the possibility of herpes simplex virus infections should be strongly considered, and empirical treatment with intravenous acyclovir should be instituted after obtaining appropriate herpesvirus studies.

## NONSPECIFIC THERAPY

### Mild, Nonspecific Febrile Illness

In infants in whom fever is the only symptom, careful observation is most important. Many infants who eventually become severely ill have 2 to 3 days of fever initially without other localized findings. Care should be taken to administer adequate fluids to febrile infants, and excessive elevation of temperature should be prevented, if possible.

### Sepsis-like Illness

In infants with severe sepsis-like illness, the major problems are shock, hepatitis and hepatic necrosis, and disseminated intravascular coagulation. For shock, attention should be directed toward treating hypotension and acidosis and ensuring adequate oxygenation.

For hepatitis, oral neomycin (25 mg/kg every 6 hours) or other nonabsorbable antibiotics to suppress intestinal bacterial flora may be helpful. The administration of blood (i.e., exchange transfusion) and vitamin K may be useful when bleeding occurs because of liver dysfunction. Heparin therapy should be considered when disseminated intravascular coagulation occurs.

### Myocarditis

There is no specific therapy for myocarditis. Congestive heart failure and arrhythmias should be treated by the usual methods. In administering digitalis preparations to infants with enterovirus myocarditis, careful attention to the initial dosage is most important because the heart is often extremely sensitive; frequently, only small amounts of digoxin are necessary.

### Meningoencephalitis

In patients with meningoencephalitis, convulsions, cerebral edema, and disturbances of fluid and electrolyte balance occur frequently and respond to treatment. Seizures are best treated with phenobarbital, phenytoin (Dilantin), or lorazepam. Cerebral edema can be treated with urea, mannitol, or large doses of corticosteroids. It seems unwise to use corticosteroids in active enterovirus infections, however, because the potential benefits may be outweighed by deleterious effects. Fluids should be monitored closely, and serum electrolyte levels should be assessed frequently because inappropriate antidiuretic hormone secretion is common.

### Paralytic Poliomyelitis

Infants should be observed carefully for evidence of respiratory paralysis. If respiratory failure occurs, the early use of a positive-pressure ventilator is essential. In newborns, this is better performed without tracheotomy. Careful attention to pooling of secretions is important. Blood gas levels should be monitored frequently. Passive exercises of all involved extremities should be started if the infant has been afebrile for 3 days.

# PREVENTION

## IMMUNIZATION

Congenital and neonatal poliomyelitis should be illnesses of historical interest only. Because segments of populations in a few regions of the world have not been

*References 68,71,441,446,533–535,541.

adequately immunized with poliovirus vaccines, however, clinical poliomyelitis continues to occur. In adequately immunized populations, congenital and neonatal poliomyelitis have been eliminated.

Attenuated viral vaccines for other enteroviruses are unavailable. If a virulent enterovirus type became prevalent, however, it is probable that a specific vaccine for active immunization could be developed.

Passive protection with intramuscular immunoglobulin (0.15 to 0.5 mL/kg) or perhaps intravenous immunoglobulin can be useful in preventing disease [538–540, 545–548]. In practice, this approach seems to be worthwhile only in sudden and virulent nursery outbreaks. If several cases of myocarditis occurred in a nursery, it would seem wise to administer immunoglobulin to all infants in the nursery. Pooled human immunoglobulin in most instances can be expected to contain antibodies against coxsackieviruses B1 through B5 and echovirus 11. This procedure could offer protection to infants without transplacentally acquired specific antibody who had not yet become infected.

## OTHER MEASURES

Breast-feeding should be encouraged in all newborns. Sadeharju and associates [546] found that infants exclusively breast-fed for longer than 2 weeks had fewer enterovirus infections by the age of 1 year compared with infants exclusively breast-fed for 2 weeks or less.

Careful attention to routine nursery infection control procedures is important in preventing and controlling epidemics of enterovirus diseases. Nursery personnel should exercise strict care in washing their hands after handling each infant. It is also important to restrict the nursery area to personnel who are free of even minor illnesses. Nursery infection, when it occurs, is best controlled in units that follow a cohort system. When illness occurs, the infant in question should be immediately isolated, and the nursery should be closed to all new admissions.

CHAPTER 25

# HEPATITIS

Wikrom Karnsakul ⚙ Kathleen B. Schwarz

CHAPTER OUTLINE

Knowledge about the hepatotropic viruses has grown dramatically in the past century, with contributions from clinicians, molecular virologists, immunologists, and pharmacologists. For the last decade, several government and nongovernment organizations have held consensus conferences on the management of acute and chronic viral hepatitis to update previous management recommendations. This chapter reviews updated information on the hepatotropic viruses (hepatitis A through G viruses and transfusion-transmitted virus [TTV]), with a particular focus on pregnant women and young infants and breakthroughs in vaccine development and global preventive measures (Table 25–1).

## HEPATITIS A VIRUS

Hepatitis A virus (HAV) is one of the most common communicable diseases and has a worldwide distribution, with estimated recognized cases of 1.5 million annually [1]. The rate of HAV in the United States has declined by 89% since the first availability of hepatitis A vaccine in 1995 [2,3]. In May 2006, the Advisory Committee on Immunization Practices recommended routine HAV vaccination for all children beginning at 12 months of age [4]. The same year, the lowest incidence of HAV ever was recorded at 1.2 per 100,000 [5]. Routine HAV immunization is close to cost-neutral on a cost-per-quality-adjusted-life-year basis [6].

### EPIDEMIOLOGY AND TRANSMISSION

In the United States, person-to-person transmission through the fecal-oral route is the primary mode of HAV transmission [7]. Infections usually result from a contact from a family member or a sex partner. In most infected individuals, the stool contains a higher concentration of virus and is likely highly contagious during the 1 to 2 weeks before the illness compared with later in the course [1]. The risk of transmission subsequently diminishes by 1 week after onset of jaundice [8]. HAV can be detected in stool for longer periods, however, especially in neonates and young children [9]. Most index cases who are usually unaware of this risk are international travelers to developing countries, regardless of travel budget, who account for 11% of documented cases of infection without a known source [10].

In one study, 84% of all known reported cases of HAV were travelers from Mexico [11]. Other risk groups for transmission are people who live with or have sex with an infected person, people living in areas where children are not routinely vaccinated against HAV (where outbreaks are more likely in children attending day care and day care employees), men who have sex with men, and illicit drug users. Water-borne outbreaks can occur, but are uncommon in developed countries with well-maintained sanitation and water supply systems.

Cooked foods also can transmit HAV if the temperature during food preparation is inadequate to kill the

virus, or if food is contaminated after cooking, as occurs in outbreaks associated with infected food handlers [1]. Foods such as lettuce, tomatoes, green onions, strawberries, raspberries, and shellfish have been associated with the outbreaks. Contamination can occur during growing, processing, or food preparation. In November 2003, a large unprecedented HAV outbreak was identified among patrons of a single Pennsylvania restaurant where mild salsa containing green onions grown in Mexico was prepared and was the source of HAV in these cases [7]. An extended study using biomarkers placed on the soil showed that HAV can contaminate the inside of the growing onion and can be taken up intracellularly through the roots [12].

The age at infection varies with socioeconomic status and associated living conditions. In developing countries particularly of high endemicity, infection usually occurs during the 1st decade of life. In the United States, the rate of HAV declined after vaccine introduction in 2002 [13]. Pockets of high prevalence still remain, however, emphasizing the importance of adhering to the recommendation for universal childhood vaccination.

Maternal-to-fetal transmission has been reported in mothers with acute icteric HAV 1 week to several weeks before delivery [14–17]. Nosocomial transmission is unusual, but outbreaks caused by transmission from hospitalized patients to health care staff have been reported [9,18]. In addition, outbreaks have occurred in neonatal intensive care units from neonates receiving infected transfused blood and subsequently transmitting HAV to other neonates and health care staff [9,18].

## MICROBIOLOGY

HAV is a single-stranded RNA virus classified as a member of the picornavirus group (Fig. 25–1). Most human strains belong to genotype I or III [8]. The three major proteins of viral capsid—VP1, VP2, and VP3 (structural proteins)—are encoded by P1 region on viral genome. The structural arrangement of capsid proteins VP1 and VP3 forms a single, dominant, serologic epitope on the virus capsid and accounts for a neutralizing antibody response. The virus can be stable in the environment for several months. HAV can live outside the body for months, which is likely explained by the slow translation rate, depending on the environmental conditions [19].

## PATHOGENESIS

HAV crosses through the gastrointestinal tract by an uncharacterized mechanism to the liver, where it solely replicates in hepatocytes [20]. The pathogenetic mechanism leading to liver tissue injury by HAV is not a viral cytopathogenic effect. Rather, it is suggested to be an immunopathologic reaction of sensitized cytotoxic T lymphocytes against infected hepatocytes where these T lymphocytes are present as an antiviral reaction similar to that directed against hepatitis B virus (HBV) [8,21]. A low translation rate and RNA replication rate may play a role in escaping host cell defenses [19]. Almost all individuals infected with HAV develop IgG and IgM antibodies to VP1 [8].

## PATHOLOGY

After the availability of serology to confirm HAV, a liver histopathology study was performed in patients with acute viral hepatitis caused by HAV ($n = 86$) or HBV ($n = 78$). The liver parenchymal changes in patients with HAV, including focal necrosis, hepatocellular ballooning, and acidophilic degeneration, were milder than changes seen in patients with HBV, but the degree of portal inflammation seemed similar in these two groups [22].

## CLINICAL MANIFESTATIONS

HAV typically is an acute, self-limited illness associated with fever, malaise, jaundice, anorexia, nausea, and abdominal discomfort after an incubation period of approximately 28 days (range 15–50 days) [1]. The appearance of jaundice usually leads to further investigation and the diagnosis of HAV; however, 70% of infected children younger than 6 years are anicteric or have a mild flulike illness. Jaundice is observed in only 7% of children younger than 4 years old [23]. In contrast, older children and adults usually are symptomatic, with jaundice occurring in 70% or more, and infection typically lasts several weeks. Symptoms usually last less than 2 months, although 10% to 15% of individuals with HAV have prolonged or relapsing hepatitis for up to 6 months.

A significant number (69%) of pregnant women with acute HAV infection during the second and third trimesters of pregnancy have gestational complications leading to preterm labor, including premature contractions, placental separation, and premature rupture of membranes [24,25]. Although uncommon, neonatal cholestasis resulting from maternal-to-fetal transmission has been reported [26,27]. Four cases of intrauterine infection have been reported. Two mothers had symptomatic HAV at 20 and 13 weeks of gestation. The fetuses developed ascites, meconium peritonitis, and perforation of the distal ileum in utero, requiring surgery after birth. The newborn infants subsequently recovered. In two other mothers with HAV at 20 days before delivery, infants developed neonatal icteric hepatitis A on day 3 of life and had a full recovery [27,28]. Mild acute hepatitis in newborn infants followed the onset of hepatitis in their mothers developing in the late third trimester (gestational week >33) probably resulting from a perinatal contact with infected blood or feces [14–17].

Although typically self-limited, HAV can be potentially life-threatening, with an estimated fatality rate of 0.3% to 0.6% reaching 1.8% among adults older than 50 years [7]. Fulminant hepatitis is rare, but is more common in people with underlying liver disease [29]. Chronic infection does not occur with HAV [23]. Rare extrahepatic manifestations include pancreatitis, renal failure, arthritis, vasculitis, thrombocytopenia, aplastic anemia, red blood cell aplasia, transverse myelitis, and toxic epidermal necrolysis [5].

## DIAGNOSIS

Serologic tests for HAV-specific total and IgM antibody are available commercially [1]. Serum IgM is present at the onset of illness and usually disappears within 4 months, but may persist for 6 months or longer [1]. The presence of serum IgM may indicate current infection, recent infection, or HAV vaccination, although false-positive results can occur. Anti-HAV IgG is detectable shortly after the appearance of IgM. The presence of anti-HAV IgG alone indicates past infection and immunity.

## TREATMENT

Treatment generally is supportive. In addition to standard precautions, contact precautions are recommended for diapered and incontinent patients for at least 1 week after onset of symptoms [1]. One of the most important aspects of management of infected individuals is active and passive immunization of close contacts (see “Prevention” next). Some patients with cholestasis may not tolerate a fatty diet. In individuals with fulminant hepatitis or liver failure, specific management is determined by the complications, and evaluation for liver transplant may be required [8].

## PREVENTION

HAV vaccination is recommended and licensed for all children 1 to 18 years old, for adults who are at increased risk for infection, for adults who are at increased risk for complications from HAV such as persons with underlying liver disease, and for any person wishing to obtain immunity to HAV. Although the vaccine is well tolerated even in studies of the safety and immunogenicity in young infants 2 to 6 months of age, the presence of passive maternal HAV antibody during the first 6 to 12 months of life interferes with vaccine immunogenicity [30–34].

HAV vaccines are given intramuscularly in a two-dose schedule with a 6- to 12-month interval [1]. Doses and schedules for HAV vaccines and formulations produced by different manufacturers are recommended by the American Academy of Pediatrics (AAP) [1]. Current HAV vaccines have been shown to be safe, to be highly immunogenic, and to confer long-lasting protection. Vaccine-induced antibodies persist for longer than 12 years in vaccinated adults, and mathematical modeling predicts antibody persistence for longer than 25 years in greater than 95% of vaccine recipients [35].

Intramuscular immunoglobulin is more than 85% effective in preventing symptomatic infection when given within 2 weeks after the most recent exposure to HAV in a household or sexual contact [1]. Immunoglobulin and the first dose of vaccine can be administered simultaneously when travel plans are imminent. Acute HAV infection during pregnancy and perinatal transmission seem to be rare, especially at the time of delivery. There have been no data to suggest cesarean infection as a mode of delivery for HAV-infected pregnant women; infants born via vaginal delivery to mothers with acute HAV infection have a favorable outcome [24]. The infant usually has exposure to HAV before the diagnosis is made in the mother. HAV has been shown in breast milk, but only one newborn case of HAV transmission in breast milk has been reported [14]. Although the efficacy has not yet been established, immunoglobulin (0.02 mL/kg) is advised to be administered to the infant if the mother’s symptoms of HAV began between 2 weeks before and 1 week after delivery [1]. To prevent nosocomial

transmission, particularly in the neonatal intensive care unit or newborn nursery, the infected mother and the neonate should be isolated, and careful hygiene practices should be emphasized [36].

Because acute HAV infection during pregnancy is associated with a high risk of maternal complications and preterm labor, HAV serology and maternal immunization during prenatal or prepregnancy evaluation could be considered in areas in which adult populations are susceptible to HAV. As the prevalence of early HAV infection seems to be decreasing in countries that are moving from high to intermediate endemicity, it is expected that an increased number of adolescents and adults susceptible to symptomatic disease may be associated with greater morbidity, mortality, and treatment costs [35].

## HEPATITIS B VIRUS AND HEPATITIS D VIRUS

HBV is believed to have infected 2 billion persons worldwide; more than 350 million individuals are currently infected [37]. The maternal-to-fetal route of transmission is responsible for most infections. Past efforts to prevent this route of transmission resulted in the strategy of providing a combination of passive and active immunization within 24 hours of birth. Although this strategy is 90% to 95% effective when properly administered, remaining areas of concern are the need to disseminate this practice for all high-risk infants and to achieve universal vaccination of all infants, as recommended by the World Health Organization. In addition there is a need to develop effective measures to prevent transmission in 100% of newborns born to infected mothers. Such measures would be highly cost-effective given the ongoing morbidity and mortality from HBV, which accounts for 500,000 to 1 million deaths from cirrhosis, liver failure, and hepatocellular carcinoma worldwide per year [38].

The delta virus (hepatitis D virus [HDV]) is always linked to HBV because it requires the surface coat of HBV for replication. Little information exists regarding perinatal transmission of HDV; even in highly endemic areas, infection with HDV is infrequent in infants and is mainly acquired during the 2nd and 3rd decades of life, suggesting a horizontal rather than vertical transmission of the virus [39].

### EPIDEMIOLOGY AND TRANSMISSION

Before the development of the combination vaccination strategy (hepatitis B immunoglobulin [HBIG] plus vaccine) for high-risk neonates, most neonates born to HBV-infected mothers were infected with HBV. Chen and colleagues [40]. reported that the presence of HBV surface antigen (HBsAg) in gastric aspirates of newborns was strongly associated with the acquisition of HBsAg by the infants; there was no correlation between the rate of infant antigenemia and the duration of the first stage of labor, and cesarean section did not decrease the rate of vertical HBV transmission.

Sexual intercourse in the second trimester of pregnancy has also been implicated in HBV intrauterine transmission [41]. Mothers positive for hepatitis B early antigen (HBeAg) and mothers with very high serum DNA levels (e.g., $\geq 10^9$ copies/mL) have the greatest risk of transferring HBV to their offspring despite adherence to the recommended combination of active and passive immunization of newborns within 24 hours of birth [42]. In one Chinese study, 7.4% of infants born to HBV-infected mothers were infected with HBV during the 1st year of life, despite receiving passive and active immunoprophylaxis in the immediate newborn period [43]. Even in countries such as Canada, where the government mandates screening of all pregnant women for HBV and provides prophylaxis to infants born to HBV-infected women, less than 85% complete prophylaxis and serologic follow-up was documented, suggesting that there is a need for public health programs with more effective universal neonatal immunization for infants at highest risk of HBV acquisition [44]. Although HBsAg can be detected in the breast milk of HBV-infected mothers, several studies have shown there is no additional risk of transmission of HBV to breast-fed infants of infected mothers, provided that proper active and passive immunoprophylaxis is carried out [45].

### MICROBIOLOGY

HBV is a well-characterized, partially double-stranded DNA virus (Fig. 25–2). HBsAg is the hallmark of chronic infection. This marker is the first to appear in acute infection. The presence of HBsAg for 6 months or more connotes chronic infection. HBeAg is associated with infectivity and indicates active replication of HBV.

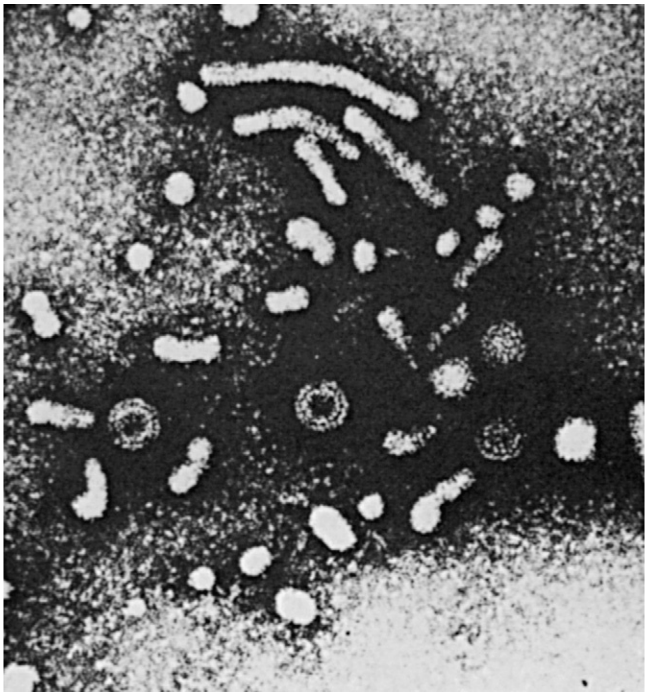

**FIGURE 25–2 Hepatitis B virus (HBV) particles.** Electron micrograph from a patient with acute HBV infection demonstrates three circulating particles: 20-nm structures and filamentous structures containing HBsAg envelope proteins (primarily the S, or major protein, but no HBV viral genome); and the 47-nm infectious virion structures containing both envelope proteins and a nucleocapsid containing genomic HBV DNA. HBSAg, hepatitis B surface antigen. *(Courtesy of Dr. June Almeida.)*

More recent reports have described “occult HBV,” as defined by the presence of HBV DNA in serum or tissue in the absence of other markers. There are now several HBV genotypes, and knowledge is emerging regarding their clinical significance. It is recognized that HBV genotype C is associated with an increased risk of development of hepatocellular carcinoma as are the basal core promoter mutant and the pre-S deletion mutant [46]. Whether or not there is a role for quantification of HBV antigens or intrahepatic HBV covalently closed circular DNA, or both, is currently under investigation.

## PATHOGENESIS

HBV is thought to cause liver injury in immunocompetent subjects via cytotoxic T cells directed to the infected hepatocyte. Functionally impaired dendritic cells may play a role in viral persistence [47], and B and T cells are involved in viral clearance. In immunocompromised subjects, such as individuals who have undergone liver transplantation, the virus itself may be hepatotoxic because HBV recurrence in the allograft is associated with poor patient and graft survival. The HB-X protein is a transcriptional activator of cellular genes and may play a role in the hepatocarcinogenesis of HBV via effects on apoptosis, DNA repair, mitogen-activated protein kinase, and JAK/STAT pathways [48].

## PATHOLOGY

There are few reports of HBV hepatic histopathology in young infants, although hepatocellular carcinoma has been reported at 8 months of age [49]. In case series of children with active HBV hepatitis enrolled in antiviral trials, liver biopsy specimens generally show mild to moderate inflammation and mild to moderate fibrosis [50]. HBV infection has been associated with immune complex disease in nonhepatic organs. Clinical manifestations include membranoproliferative glomerulonephritis, cryoglobulinemia, Gianotti-Crosti papular acrodermatitis of childhood, and arthritis.

## CLINICAL MANIFESTATIONS

The clinical manifestations of HBV infection depend on the age of acquisition. Neonates have a greater than 90% risk of chronic infection, and children and adolescents have a 25% to 50% risk; chronic infection is observed in only 5% of adults exposed to HBV [51]. Most newborns who acquire HBV remain in the immunotolerant stage for 1 or 2 decades. This stage is characterized by HBsAg and HBeAg antigenemia, high levels of HBV DNA, normal or minimally elevated serum aminotransferases, and minimal inflammation in the liver biopsy specimen. Approximately 6% of infants born to mothers who are positive for anti–hepatitis B early antibody develop acute hepatitis at 2 months of age [52]. Infants are ill with fever, jaundice, and hepatic tenderness. Serum aminotransferases are elevated, and there is active inflammation in the liver biopsy specimen. About one third of older children and adolescents with acute HBV develop these classic symptoms [53].

Most infants, children, and adolescents have chronic infection (lasting >6 months) of the asymptomatic immunotolerant type. In infants who are perinatally infected, the estimated spontaneous clearance of HBV is 0.6% per year over the 1st decade of life, but in subjects infected as adolescents and adults, the rate of clearance is 1.8% per year [54]. A few young subjects have active hepatitis with elevation of serum aminotransferases and active inflammation in the liver biopsy specimen. These subjects are most likely to respond to antiviral treatment. Inactive carriers are characterized by HBsAg positivity, seroconversion of HBeAg to anti–hepatitis B early antibody, undetectable HBV DNA, and normal serum aminotransferases.

Individuals with active hepatitis are at greatest risk for developing cirrhosis and hepatocellular carcinoma, but there is a growing concern that persistently high levels of HBV DNA for decades, even in immunotolerant subjects, are associated with an increased risk of hepatocellular carcinoma [55]. In one Chinese study, HBV infection in pregnancy was associated with high rates of complications (abortion, 16.7%; preterm births, 43%; neonatal asphyxia, 15.6%; and fetal death, 4.5%) [56].

## DIAGNOSIS

The diagnosis of HBV is most commonly made by the presence of HBsAg in the circulation. Other studies commonly performed include HBeAg, HBV DNA, and anti–core antibody (Fig. 25–3). IgM anti–core antibody is indicative of recent exposure to HBV, whereas IgG core antibody is positive in individuals with chronic infection and in individuals who have cleared infection. Subjects who have been successfully immunized with HBV vaccine exhibit anti-HBsAg positivity. If a liver biopsy specimen is obtained, immunohistochemistry can be performed using an antibody against the surface antigen. Screening has been recommended for all pregnant women and for newly arrived immigrants to the United States from countries where HBV prevalence rate is 2% or greater [57]. Whether or not there should be screening of pregnant women living in areas of high HBV endemicity for occult HBV infection using sensitive assays for HBV DNA, is a matter of current study.

## TREATMENT

There are currently two treatments for chronic HBV infection in children 2 to 18 years old approved by the U.S. Food and Drug Administration (FDA): standard α-interferon, which is given parenterally three times a week for 16 to 24 weeks, and lamivudine, which is given via the oral route. Interferon therapy should not be given to infants younger than 1 year because of the risk of spastic diplegia; in older children, side effects are common and are usually flulike in nature. Drug resistance has not been a problem. When interferon is administered to children with active hepatitis B, 20% to 58% show undetectable HBV DNA or HBeAg, or both, in serum [58]. Lamivudine is much better tolerated by children than interferon, but drug resistance is common—approximately 20% per year of administration. Currently complete and ongoing

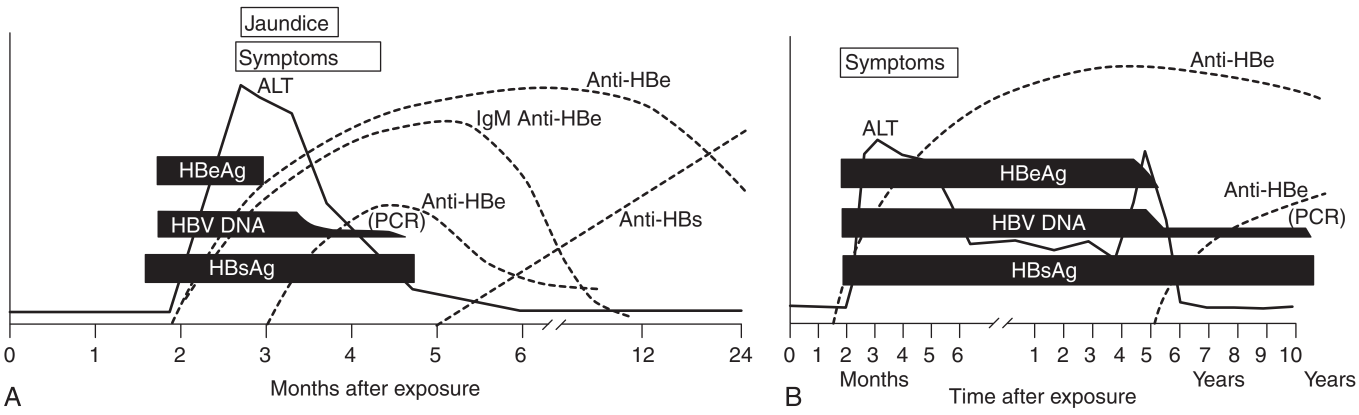

**FIGURE 25–3 Viral and host serologic markers and clinical correlates of hepatitis B virus (HBV) infection. A,** Acute infection with appropriate host response and resolution of infection. **B,** Chronic infection. *(Data from Servoss JC, Friedman LS. Serologic and molecular diagnosis of hepatitis B virus. Clin Liver Dis 2004;8[2]:267-81.)*

pediatric trials of more potent nucleoside/nucleotide analogues include adefovir dipivoxil and entecavir [59].

## PREVENTION

Detailed HBV vaccine schedules are available from the AAP *Red Book* [1]. Schedules are provided for the various pediatric age groups, for vaccination of preterm infants, and for newborns depending on maternal HBsAg status (Table 25–2). Systematic HBV vaccination has markedly decreased the incidence of new HBV infections in the pediatric age group over the last 2 decades. Although much less is known about the impact of HBV vaccine programs on HDV incidence, one Italian study showed the incidence decreased from 1.7 to 0.5 cases per 1 million population after introduction of the universal anti-HBV campaign [60]. Efforts have been made to assess the impact of maternal HBV screening on perinatal HBV vaccination. In a U.S. study, to assess the completeness of maternal screening for newborn prophylaxis, the mother's HBsAg status was known within 12 hours of delivery for 84% of mothers screened; however, of the infants whose mothers' HBsAg status was unknown, only 28% were vaccinated the 1st day of life [61].

**TABLE 25–2** Hepatitis B Neonatal Intervention Strategies Based on Maternal Hepatitis B Virus (HBV) Screening Status*

| Maternal HBV Status | Interpretation | Laboratory Evaluation at Birth and during Infancy | Infant Treatment |
|---|---|---|---|
| HBsAg-positive | Mother is infectious; significant risk of neonatal infection | HBsAg on peripheral venous blood sampling to diagnose intrauterine infection; check infant after age 9 mo for anti-HBs and HBsAg | *All infants*: HBIG 0.5 mL ≤12 hr after birth; in addition, 12 hr after birth, second and third doses of vaccine for infants with birth weight ≥2000 g as for HBsAg-negative status<br>*Preterm infants <2000 g birth weight*: Initial birth dose should not be counted as one of immunizing series because of immature response to vaccine; subsequent 3 immunizations in primary immunizing series for these infants should start at age 1–2 mo |
| HBsAg status unknown | Mother's infectious status should be determined by HBsAg testing as soon as possible | None required at birth; in infants whose mothers are subsequently found to be HBsAg-positive, check infant after age 9 mo for anti-HBs and HBsAg | *Full-term infants*: Give first dose of hepatitis B vaccine ≤12 hr of birth; if maternal HBsAg is positive, give HBIG 0.5 mL as soon as possible, ≤7 days of age; if maternal HBsAg is negative, HBIG is not needed; subsequent doses as for HBsAg-negative status<br>*Preterm infants <2000 g birth weight*: If maternal HBsAg status cannot be determined ≤12 hr of birth, give HBIG in addition to hepatitis vaccine ≤12 hr of birth; provide subsequent 3 hepatitis B immunizations for primary series, starting at 1 mo of age, as above for preterm infants |
| HBsAg-negative | Mother is not considered infectious; no risk to neonate | None required | *All newborn infants*: Standard 3-dose immunization regimen with hepatitis B vaccine recommended: dose 1 given soon after birth before discharge, dose 2 given at 1–2 mo of age at least 4 wk after dose 1; dose 3 given at 6–18 mo, at least 16 wk after dose 1, and at least 8 wk after dose 2, with last dose not before 24 wk of age |

**This table recommends only single-antigen vaccine; for single-antigen vaccine combination, refer to* Red Book 2006 *recommendation [1].*
*HBIG, hepatitis B immunoglobulin; HBsAg, hepatitis B surface antigen.*

HBV DNA virus levels increase during the last trimester of pregnancy and early in the postpartum period; the value of assessing these levels to modify immunoprophylaxis of the newborn is a matter of current study [62]. Although serum alanine aminotransferase levels are often used as surrogate markers of HBV DNA in HBeAg-negative pregnant women, they do not seem to correlate well with these levels [63]. Because of possible in utero HBV transmission among pregnant women with high HBV DNA titers, studies have been done regarding the utility of the possible added efficacy of using HBIG during the third trimester of pregnancy to prevent maternal-to-fetal transmission of HBV; results to date have been conflicting. One study reported that protective anti-HBsAg rates at 6 months were higher in infants born to either HBeAg-positive or HBeAg-negative mothers who had received three doses of HBIG in late pregnancy along with infant passive and active immunization [64]. Another study showed no difference in the protective efficacy rates assessed at 12 months of age in infants of mothers receiving HBIG or not receiving HBIG [65].

Although the high efficacy of neonatal HBV vaccination suggests that most cases are transmitted perinatally, some neonates who have failed vaccine have been found to be positive for HBsAg or HBeAg at birth, suggesting intrauterine transmission [66]. There is a need to elucidate the role of nucleoside/nucleotide agents in treating chronic HBV in the last part of pregnancy in women with high HBV DNA levels who are positive for HBeAg and who are most likely to infect their newborns [67,68].

## HEPATITIS C VIRUS

Since the discovery of hepatitis C virus (HCV) in 1989, HCV has become a global public health problem, infecting approximately 170 million individuals. Although transfusion-transmitted HCV was the major form of HCV in the pediatric age group when the virus was first described [69], since 1992, when most blood units transfused have been free of HCV, the maternal-to-fetal route of transmission of this virus has become the dominant route for new cases of HCV. Jhaveri and colleagues [70]. estimated the direct medical costs related to HCV in childhood projected for the next decade. Expressed as U.S. dollars, these include $26 million for screening, $117 to $206 million for monitoring, and $56 to $104 million for treatment costs.

There are currently two FDA-approved treatments for HCV in children starting at age 3 years [58]. No strategy to date has been shown to be effective in interrupting maternal-to-fetal transmission, so this is a major research goal in the future.

### EPIDEMIOLOGY AND TRANSMISSION

Maternal-to-fetal transmission has been studied extensively. The prevalence of anti-HCV antibody in pregnant women is 0.1% to 2.4%, and 60% to 70% are viremic. Transmission rates are 4% to 7% when the mother is viremic, and mothers with HCV RNA greater than $10^6$ copies/mL are more likely to transmit the infection to the fetus compared with mothers with lower levels of viremia [71]. Coinfection with human immunodeficiency virus (HIV) increases the risk of transmission fourfold to fivefold, but highly active retroviral therapy may significantly decrease this risk [72]. In the setting of coinfection with HCV and HIV, there is no evidence that HCV neutralizing antibodies are associated with the prevention of maternal-to-fetal transmission of HCV [73].

Female infants are more likely than male infants to acquire HCV from their mothers [74]. One Japanese study, which reported higher maternal-to-fetal transmission rates than most (14.2%), found positive associations between transmission rate and maternal viral load, liver dysfunction, and blood loss of >500 mL at delivery [75]. Although it is unknown when during pregnancy and delivery HCV transmission occurs, one study suggested that one third to one half of infants acquiring HCV from their mothers were infected in utero [76].

### MICROBIOLOGY

HCV is a well-characterized, single-stranded enveloped RNA virus 10 kb in length and 30 to 60 nm in diameter. It contains a single open reading frame that encodes a polyprotein of approximately 3000 amino acids. There are three structural proteins—one core and two envelope (E1 and E2)—and five nonstructural proteins (NS2, NS3, NS4A, NSB, and NS5B). The related genes encode the NS2-3 protease, the NS3/NS4A serine protease, and the NS5B RNA-dependent RNA polymerase [77]. The polyprotein undergoes cleavage by cellular and viral proteases to yield functional proteins. Tissue culture studies in the past had employed replicon systems that produced viral proteins but not infectious virions. In 2005, Kato and Wakita [78] reported a major breakthrough when they were able to culture the JFH-1 HCV virus in Huh 7 cells to produce infectious virions. There are at least six genotypes of HCV and more than 50 subtypes; genotypes differ at 31% to 34% of nucleotide positions on pairwise comparisons of complete sequences, and there is a similar difference between encoded polyproteins. The major utility of the genotypes so far has been to characterize differential susceptibility to antiviral treatments, with genotypes I and IV being most resistant to interferon-based therapies.

### PATHOGENESIS

HCV is not considered a cytopathic virus. Viral clearance and hepatic injury are related to the immune response to the virus. The antigen nonspecific arm is the first line of defense and consists of natural killer cells, neutrophils, and macrophages. Dendritic cells assume the role of professional antigen-presenting cells; these induce the virus-specific immune response from $CD4^+$ T helper cells, B cells, and $CD8^+$ cytotoxic T cells. The liver is the only known site of viral replication because negative RNA is detected only in the liver. The immunopathogenesis of HCV liver disease is still being elaborated, but cytokines and Fas ligand–induced apoptosis of hepatocytes probably play major roles. Extrahepatic manifestations of HCV include mixed cryoglobulinemia, membranoproliferative glomerulonephritis, diabetes mellitus, retinopathy, peripheral neuropathy, and lymphoma; pathogenesis of these entities is under current investigation.

## PATHOLOGY

Several histologic features are characteristic of HCV, including bile duct damage, steatosis, and lymphoid follicles [79]. In a multicenter antiviral trial of children 5 to 18 years old, 121 liver biopsy specimens were reviewed at entry. Inflammation in the biopsy specimen was minimal in 42%, mild in 17%, moderate in 38%, and severe in only 3%. Five specimens had bridging fibrosis, and two had cirrhosis [80].

## CLINICAL MANIFESTATIONS

Pergam and coworkers [81] reported more recently that infants of HCV-positive mothers were more likely to have low birth weight, to be small for gestational age, to need assisted ventilation, and to require admission to a neonatal intensive care unit. HCV-positive mothers with excess weight gain also had a greater risk of gestational diabetes [81]. Cholestasis of pregnancy is increased in HCV-infected mothers [82]. The European Paediatric Hepatitis C Virus Network reported the natural history of 266 children with vertical HCV infection; approximately 20% seemed to clear the infection, 50% had evidence of chronic asymptomatic infection, and 30% had evidence of chronic active infection [83]. Children with transfusion-acquired HCV also tend to have mild asymptomatic infection, although rarely infection may proceed to decompensated liver disease and liver transplantation [84]. In another large pediatric natural history study, 1.8% of children progressed to decompensated cirrhosis (mean age 9.6 years). These children were mostly perinatally infected with genotype 1a, and most of the mothers were intravenous drug users [85].

## DIAGNOSIS

Diagnosis is usually made by screening of high-risk children for anti-HCV antibody. Infection is confirmed by HCV RNA by polymerase chain reaction (PCR) assay. The AAP recommends that infants born to HCV-infected mothers be screened by anti-HCV at 18 months postpartum because passively acquired maternal antibody can persist for 18 months [86].

## TREATMENT

There are currently two FDA-approved antiviral therapies for children: interferon plus ribavirin given three times weekly, which is indicated for children 3 to 18 years old with HCV infection, and pegylated interferon plus ribavirin given once a week, which is indicated for children 5 to 18 years old; both regimens are given for 48 weeks for children with genotypes 1 and 4. Children with genotypes 2 and 3 may require only 24 weeks of therapy similar to adults, but this has not been well studied in children. Sustained viral response (e.g., negative HCV RNA 6 months after cessation of therapy) for thrice-weekly interferon plus ribavirin is 46% [87] and for weekly pegylated interferon plus ribavirin is 59% [88]. Many small molecule inhibitors of HCV replication, such as inhibitors of the NS3 serine protease and the RNA polymerase, are being studied in adults with positive preliminary results, although none have been approved by the FDA as yet. Such therapies will be tested in children after safety and efficacy are well established in adults.

## PREVENTION

At present, there is no effective way to interrupt transmission of HCV from mother to infant. At present neither elective cesarean section nor avoidance of breast-feeding should be recommended to HCV-infected women [89], although scattered reports do show a higher risk of HCV transmission for infants whose mothers have HCV RNA in breast milk [90]. In one report, membrane rupture lasting 6 or more hours and internal fetal monitoring were associated with increased rates of transmission of HCV from mother to infant, suggesting there may be obstetric practices that can reduce transmission [37]. Others have reported an association of higher transmission rates with intrapartum exposure to virus-contaminated maternal blood secondary to a perineal or vaginal laceration [91].

HCV RNA is detectable in maternal colostrum. HCV transmission via breast-feeding has not been well documented, however. Inactivation of the virus by gastric acid and very low levels of virus in breast milk may explain this potential protective mechanism. The AAP and the American College of Obstetricians and Gynecologists support breast-feeding by mothers with HCV infection [86]. There is definitely a role for public education about risk avoidance for high-risk children and adolescents. Schwarz and colleagues [92] reported more recently that 19% of homeless caregivers were anti-HCV–positive, although no cases of HCV infection were found in the children, suggesting the importance of directing preventive education to the young.

# HEPATITIS E VIRUS

Hepatitis E virus (HEV) is endemic in many developing countries, where it is responsible for more than 50% of cases of acute viral hepatitis [93]. More recent data have shown that HEV is more common worldwide than HAV [94]. HEV is an important public health concern as a major cause of enterically transmitted hepatitis worldwide. Cases of sporadic HEV in people with no history of recent travel (autochthonous infection) in developed countries are far more common than previously thought [94]. HEV is frequently misdiagnosed as drug-induced liver injury or hepatitis of unknown etiology. HEV has a poor prognosis in patients with preexisting chronic liver disease and pregnant women in their third trimester. Patients with unexplained hepatitis should be tested for HEV, regardless of their age, demographics, or travel history.

## EPIDEMIOLOGY AND TRANSMISSION

HEV is spread through food or water contaminated by feces from an infected individual. Transmission of HEV is by the fecal-oral route. Water-borne outbreaks have often been reported in developing countries [94]. In contrast to the other agents of viral hepatitis, HEV commonly is found in wild and domestic animals, which may provide

an important source of infections in humans [94]. Person-to-person transmission seems to be much less efficient than with HAV. HEV transmission is highly endemic in Asia, the Middle East, and Africa. Sporadic HEV infection has been reported in developing countries, particularly on the Indian subcontinent, where some studies have shown HEV to be the most common etiology of acute viral hepatitis [94]. In the United States, HEV infection is uncommon and generally occurs in travelers returning from countries with high endemicity. Autochthonous infection has been reported in developed regions such as North America, Europe, Japan, New Zealand, and Australia, and a porcine zoonosis has been suggested [94,95]. Compared with HEV infections in the developing world, in developed countries most autochthonous HEV infections are reported in middle-aged and elderly men [94].

Studies in endemic regions show high seroprevalence rates of HEV ranging from 15% to 60% [96–98]. The anti-HEV seroprevalence rate reaches more than 95% in children living in endemic areas by the age of 10 years. Anti-HEV antibodies are rarely detected in children. Anti-HEV seroprevalence increases to 40% in young adults without substantial increases later in life [96]. Maternal-to-fetal transmission of HEV ranges from 23.3% [99] to 50% [100]. Acute HEV infection is severe for the mother during the third trimester of pregnancy, resulting in a mortality rate of 15% to 25% [101]. In a large prenatal study in India, 28 of 469 pregnant women were positive for HEV RNA; 12 of these women had acute liver disease, and 2 died undelivered [102]. The remaining 16 women had mild disease with full recovery. Of 26 infants born, all were positive for HEV RNA and developed acute infection [102].

## MICROBIOLOGY

HEV causing epidemic non-A, non-B hepatitis was identified in 1983 from a human challenge experiment and subsequently cloned in 1990. HEV is a spherical, nonenveloped, positive-strand RNA virus, classified as a member of the Caliciviridae family, that is approximately 32 to 34 nm in diameter [103]. Two major species of the virus are recognized: mammalian HEV, a virus that causes acute hepatitis in humans and has a reservoir in pigs and possibly a range of other mammals, and avian HEV. Four major genotypes of mammalian HEV have been reported. Genotype 1 HEV is the main cause of sporadic and epidemic HEV in developing regions of Asia, Africa, and South America. Genotype 2 has so far been identified in patients in Mexico, Chad, and Nigeria [104–106]. Genotype 3 HEV has been found in patients with autochthonous HEV in many developed regions and in pig populations worldwide [107]. Genotype 4 has been found in developed countries such as Japan, China, and Taiwan and in pig populations in those countries and India [108,109].

## PATHOGENESIS

Peak viremia occurs during the incubation period and the early acute phase of disease. Immediately before the onset of clinical symptoms, HEV RNA can be detected in the blood and stool. The concentration of serum liver enzymes increases, with a marked elevation of serum aminotransferases, peaking at about 6 weeks after exposure coincident with anti-HEV in serum and decreasing HEV antigen in hepatocytes. Infiltrating lymphocytes in the liver have been found to be a cytotoxic/suppressor immunophenotype, and this supports the role of an immune-mediated response in the pathogenesis of liver injury [110].

A few days to weeks after the onset of clinical symptoms, HEV RNA is cleared from the blood; however, the virus continues to be shed in stool for another 2 weeks [111]. Researchers have been unable to explain the high HEV morbidity in pregnancy, why it is different from other hepatitis viruses such as HAV with similar epidemiologic features, and the difference in HEV morbidity in pregnant women in different geographic regions.

## PATHOLOGY

Generally, individuals with HEV who travel from developing countries are diagnosed with serology without a liver biopsy. Few patients with autochthonous HEV require a liver biopsy because they have a self-limiting illness. In a few patients with more severe hepatitis, a liver biopsy may be required. The few data on hepatic histopathology of acute autochthonous HEV are limited to patients with severe disease. Liver histology in noncirrhotic liver is similar to that seen in other cases of acute viral hepatitis, with lobular disarray with reticulin framework distortion, portal tract expansion with severe mixed polymorphonuclear and lymphocytic inflammatory infiltrates, moderate to severe interface hepatitis, and cholangiolitis [112,113].

In patients with HEV who have underlying cirrhosis, the liver histology is nonspecific [114]. In the few transplant patients receiving immunosuppression who have developed chronic HEV infection, liver histology shows progressive fibrosis, portal hepatitis with lymphocytic infiltration, and piecemeal necrosis with progression to cirrhosis [115,116].

## CLINICAL MANIFESTATIONS

In most individuals, HEV manifests as a self-limiting, acute, icteric hepatitis with symptoms including jaundice, malaise, anorexia, fever, abdominal pain, and arthralgia. Clinical disease is more common among adults than among children. Mortality rates associated with HEV are low and are thought to be about 1% in the general population [117]. HEV is more severe in pregnant women, however, in whom mortality rates can reach 20% [118,119].

The incubation period ranges from 2 to 9 weeks. The presentation of HEV in individuals infected in developed countries seems to be similar to individuals from endemic regions; however, the mortality rate is higher, ranging from 8% to 11%. Most autochthonous HEV infections are self-limiting [94]; 8% to 11% of infected individuals develop fulminant hepatitis and liver failure. Individuals with underlying chronic liver disease can have a poor outcome with mortality approaching 70% [120,121]. A study from India showed that patients with chronic liver disease and HEV superinfection have a 1-year mortality rate of 70% [122]. Chronic HEV infection has been documented in patients receiving immunosuppressive therapy after organ transplantation [115].

## DIAGNOSIS

The antibody response to HEV infection follows a conventional course with specific IgM usually detectable at the onset of symptoms or deranged liver function, followed shortly by HEV-specific IgG [123]. Most primary serologic tests are enzyme immunoassays that use recombinant antigens derived from different strains of HEV. Conventional and real-time reverse transcriptase PCR assays have been used to detect HEV RNA in clinical specimens (mainly blood). Although reverse transcriptase PCR seems to be more sensitive than serology for HEV diagnosis, [124–126], the window of detectable HEV viremia is narrow [127]. Because patients might not present until sometime after the onset of illness, a negative result does not exclude infection.

## TREATMENT

HEV illness usually is self-limiting over several weeks to months, and treatment is supportive. Patients with preexisting chronic liver disease who develop hepatic failure as a result of HEV infection should be considered for liver transplant because such patients have a poor outcome. Administration of immunoglobulin has not been helpful in preventing the disease in HEV-endemic areas [110,128].

## PREVENTION

The only way to prevent HEV disease is to reduce the risk of exposure to the virus. The risk for HEV transmission in infants born to asymptomatic anti-HEV–positive mothers seems to be low. No data suggest cesarean section prevents HEV transmission [129]. Given the low amount of HEV in colostrum (low infectivity), breastfeeding, an important nutrition source in endemic areas, should not be discouraged [129]. Mothers with symptomatic HEV with high viral loads should be advised not to breast-feed, however, because of potential risk of transmission [129]. Although there is no FDA-approved vaccine for HEV, several vaccines are under development, including a completed phase II randomized placebo-controlled trial in Nepal of a vaccine with efficacy of 95.5% [130]. At 2 years' follow-up, only 56% of vaccinated individuals had detectable anti-HEV, however. The most important issue is the safety and efficacy of the vaccine in women because mortality is high in pregnant women and individuals with chronic liver disease infected with HEV. Other issues include the durability of vaccine-induced immunity and its cost-effectiveness.

# OTHER HEPATOTROPIC VIRUSES

Some cases of viral hepatitis cannot be attributed to the hepatitis A, B, C, D, or E viruses or even less common viruses that can infect the liver, such as cytomegalovirus, Epstein-Barr virus, herpesvirus, parvovirus, and adenovirus. These cases are called non-A–E hepatitis. Scientists continue to study the causes of non-A–E hepatitis. GB virus type C/hepatitis G virus (GBV-C/HGV) and TTV and its species variants such as SEN virus (SEN-V) have been a health care concern and received extensive investigation as possible agents of acute non-A–E hepatitis. Although they do not seem to be responsible for most sporadic acute non-A-E hepatitis cases, more research is needed.

## GB VIRUS TYPE C/HEPATITIS G VIRUS

GBV-C/HGV was discovered in 1995 with relatively high prevalence in the general population of developed countries. GBV-C/HGV is transmitted by transfusion of blood and blood products, intravenous drug abuse, sexual contact, and maternal-to-fetal transmission. The potentially hepatotropic flavivirus-like virus has been detected in a few patients with acute and chronic hepatitis and in a certain proportion of blood donors and recipients of blood or blood components [131].

### Epidemiology and Transmission

Approximately 1% to 5% of volunteer blood donors in developed countries are HGV viremic; however, the prevalence in the general population in some developing countries is 10% to 20%. GBV-C/HGV is transmitted parenterally. High-risk groups include intravenous drug users, patients with multiple transfusions, patients undergoing hemodialysis, and hemophiliacs. Transmission from mother to infant and sexual contact has been documented.

GBV-C/HGV is frequently transmitted from pregnant mothers to infants in the general population. The most critical factor is the titer of viral RNA in the maternal serum. In one study, the use of elective cesarean section in women with high titers of viral RNA resulted in decreased vertical transmission of the virus [131]. Until more is known about the pathogenesis of perinatal infection, cesarean section is not recommended for routine prevention of perinatal GBV-C/HGV infection, however.

### Microbiology

GBV-C/HGV viruses, variants of the same viral species, belong to the Flaviviridae, distantly related to HCV, and are now classified into five genotypes (West Africa, North America, Asia). GBV-C/HGV has a positive-stranded, linear RNA genome with a large open reading frame that encodes a single large polyprotein [132].

### Pathogenesis

Despite the described cases of acute and chronic hepatitis G, its hepatic tropism and the mechanism responsible for hepatitis are still unclear or controversial [132].

### Pathology

GBV-C/HGV can cause persistent infection in young infants with unclear or insignificant evidence of liver disease [132].

### Clinical Manifestations

There may be a rare association of GBV-C/HGV infection with transient elevation of aminotransferases in patients with jaundice. Only 0.3% of individuals with

acute viral hepatitis are infected with GBV-C/HGV alone. Approximately 3% to 6% of individuals with non-A–E hepatitis are GBV-C/HGV viremic. GBV-C/HGV is not the major cause of acute viral hepatitis. To date, this virus has not been associated with acute or chronic hepatitis [133]. GBV-C/HGV has not been a cause of fulminant hepatic failure and it does not have an association with hepatocellular carcinoma.

### Diagnosis

No commercial serologic tests are available. Indirect immunoassay to the envelope protein E2 is for research purposes only. E2-specific antibodies are associated with loss of detectable GBV-C/HGV RNA, which indicates recovery from GBV-C/HGV. Reverse transcriptase PCR is used for detecting GBV-C RNA in serum samples.

### Treatment

Because the virus has never been shown to cause significant symptoms or liver damage, no treatment is indicated. HGV has been reported to respond to interferon therapy, but the infection recurs when the treatment is completed [134].

### Prevention

Viral screening is not yet recommended before blood transfusion. Cesarean section is not a recommended practice to avoid maternal-to-fetal transmission of GBV-C/HGV.

## TRANSFUSION-TRANSMITTED VIRUS

In 1997, a novel DNA virus was isolated from the serum of a Japanese patient who was diagnosed with hepatitis after blood transfusion of unknown etiology [135].

### Epidemiology and Transmission

Epidemiologic studies suggest that TTV is mainly transmitted via the parenteral route and maternal-to-fetal transmission, although the fecal-oral route and sexual contact have been reported. Infection rate of TTV is higher in patients with liver diseases than in healthy donors. TTV is widespread throughout the world and can be detected in 50% to 95% of healthy persons [135]. Gerner and associates [136] suggested that TTV can be transmitted transplacentally. Transplacental transmission of TTV is possibly low and independent of viral load [135]. A study in the Republic of Congo showed that a significant number of infants acquired TTV infection at 3 months postpartum (61 [58%] of 105 women at a prenatal clinic and 36 [54%] of 68 infants); however TTV was detected in 43% of children with TTV-negative mothers (13 of 30). In addition, nucleotide sequences of TTV in these children were often unmatched with those in their mothers [137].

TTV may be transmitted early in childhood based on the evidence of higher viral copies of TTV and a high prevalence of TTV in children of all ages. Although the mechanism of postnatal transmission of TTV is unknown in some children, horizontal infection via breast-feeding could explain this because TTV was detected in breast milk from TTV-positive women whose infants were TTV-negative at both 5 days and 3 months of age, but shown to be TTV-positive at 6 months of age [138]. In addition, the breast-fed infants had an increased positive seroconversion rate of TTV with an increase in length of breast-feeding duration [139].

### Microbiology

TTV is a nonenveloped, single-stranded, and circular DNA virus with the entire sequence of 3852 nucleotides and mostly resembles the members of the Circoviridae family. It is classified into 16 genotypes [140]. TTVs are extraordinarily diverse, spanning five groups including SANBAN and SEN viruses. Recombination between variants is frequent. The extremely high sequence divergence of TTV strains explains a mixed infection with different genotypes in the same individual. It is unclear how TTVs could be viable and why they require such genetic variation.

### Pathogenesis

TTV can infect not only hepatocytes, but also extrahepatic tissues such as bone marrow. Although the pathogenicity of TTV is thought to be comparatively weak, it was postulated to cause liver damage in some studies [140].

### Pathology

Histologic activity indices in patients with chronic HCV infection coinfected with TTV were higher than patients with HCV infection alone; however, the pathogenicity and clinical significance of TTV remain unclear at present [141].

### Clinical Manifestations

TTV is a virus frequently isolated from patients with various types of viral hepatitis, from patients presenting with hepatitis of unknown etiology, and from healthy individuals. TTV has no effect on biochemical markers of associated viral hepatitis. It may be associated with a mild form of non-A–E hepatitis [142]. Although the mechanism of persistent TTV viremia is not well understood, a significant difference of liver biochemistry is not observed among healthy children with isolated TTV infection and children with HBV and HCV infection with TTV coinfection [143].

### Diagnosis

No serologic test is currently available. The viral DNA has been detected by PCR.

### Treatment

In cases of coinfection with HCV, TTV eradication was observed in some patients with interferon treatment, but the TTV DNA was detected again after the treatment [144]. Because there is substantial controversy regarding the disease-causing potential of TTV, interferon therapy for TTV is not routinely recommended.

### Prevention

TTV screening is not yet recommended before blood transfusion. Cesarean section has not been a recommended practice to avoid maternal-to-fetal transmission of TTV.

## CONCLUSION

Translational research has made many contributions to knowledge about the hepatotropic viruses, but knowledge gaps remain. The incidence and health care costs related to HAV should decrease dramatically with the use of the highly effective hepatitis A vaccine for all subjects 1 to 18 years old; universal vaccination for all adults as well may be a more practical strategy, rather than targeted immunization in high-risk groups. More effective strategies are needed to prevent maternal-to-fetal transmission of HBV because vaccine failures still occur in at least 10% of mother-infant pairs. New data have emerged in recent years on the natural history and treatment of chronic HBV infection in children, but antiviral resistance remains a main concern during long-term treatment of chronic HBV. Advances have been made in treatment of HCV in children, and promising results are seen with specifically targeted antiviral therapies. A novel hepatitis E vaccine was shown to be efficacious; however, more investigations to improve immunogenicity and safety are needed, especially for pregnant women, in whom morbidity and mortality are high. Close observations of HGV and TTV are needed to see if these viruses are truly of clinical significance.

CHAPTER 26

# Herpes Simplex Virus Infections

**Kathleen M. Gutierrez ✪ Richard J. Whitley ✪ Ann M. Arvin**

## CHAPTER OUTLINE

Neonatal herpes simplex virus (HSV) infection was identified as a distinct disease almost 75 years ago. The first written descriptions of neonatal HSV were attributed to Hass [1], who described the histopathologic findings of a fatal case, and to Batignani [2], who described a newborn infant with HSV keratitis. During subsequent decades, understanding of neonatal HSV infections was based on histopathologic descriptions of the disease, which indicated a broad spectrum of organ involvement in infants.

An important scientific breakthrough occurred in the mid-1960s, when Nahmias and Dowdle [3] showed two antigenic types of HSV. The development of viral typing methods provided the tools required to clarify the epidemiology of these infections. HSV infections "above the belt," primarily of the lip and oropharynx, were found in most cases to be caused by HSV type 1 (HSV-1). Infections "below the belt," particularly genital infections, were usually caused by HSV type 2 (HSV-2). The finding that genital HSV infections and neonatal HSV infections were most often due to HSV-2 suggested a cause-and-effect relationship between these two entities. This causal relationship was strengthened by detection of the virus in the maternal genital tract at the time of delivery, indicating that acquisition of the virus occurs by contact with infected genital secretions during birth.

DOI: 10.1016/B978-1-4160-6400-8.00026-2

Knowledge of HSV structure and function, epidemiology, natural history, and pathogenesis of neonatal HSV infection has increased during the past 3 decades [4]. The development of antiviral therapy represented a significant advance in the management of infected children and has substantially decreased the morbidity and mortality associated with neonatal HSV infections. Neonatal HSV infection is more amenable to prevention and treatment than many other pathogens because it is acquired most often at birth rather than in utero. Postnatal acquisition of HSV-1 has been documented from nonmaternal sources, and more cases caused by HSV-1 infections of the maternal genital tract have been identified recently. Perspectives on the changing presentations of neonatal HSV infection, the obstacles to diagnosis, and the value of antiviral therapy are addressed in this chapter.

# HERPES SIMPLEX VIRUS

## STRUCTURE

HSV-1 and HSV-2 are members of the large family of herpesviruses [4]. Other human herpesviruses include cytomegalovirus, varicella-zoster virus, Epstein-Barr virus, and human herpesviruses 6A, 6B, 7, and 8. Structurally, these viruses are virtually indistinguishable. The viral DNA genome is packaged inside an icosahedral capsid that is surrounded by a layer of proteins called the *tegument*. A lipid envelope that contains viral glycoproteins surrounds the capsid and tegument. These glycoproteins mediate virion attachment and entry into cells.

The HSV-1 and HSV-2 genomes consist of approximately 150,000 base pairs and encode more than 100 proteins [4]. The viral genomes consist of two components, L (long) and S (short), each of which contains unique sequences that can invert, generating four isomers. Viral genomic DNA extracted from virions or infected cells consists of four equal populations that differ in the relative orientation of these two unique components. Although the two viruses diverged millions of years ago, the order of genes in the HSV-1 and HSV-2 genomes follows the same linear pattern, and most genes have counterparts in both viruses. The nucleotide sequence of related genes and the amino acid residues of the proteins they encode often differ significantly, however [5,6]. The two viral types can be distinguished by using restriction enzyme analysis of genomic DNA or, more recently, by sequencing of selected genes or regions of the genome, which allows precise epidemiologic investigation of virus transmission.

## REPLICATION

HSV replication is characterized by the transcription of three gene classes, α, β, and γ, that encode viral proteins made at immediate-early, early, and late times after virus entry into the cell [4]. Many of these genes can be removed from the viral genome without blocking the capacity of the virus to replicate in cultured cells, but most have important functions during infection of the host. The HSV genome can also be manipulated to insert foreign genes without inhibiting viral replication. Mutations that modify the virulence of HSV-1 and HSV-2 may provide an opportunity to design genetically engineered herpesviruses for use as vaccines [7].

HSV α genes are expressed at immediate-early times after infection and are responsible for the initiation of replication. These genes are transcribed in infected cells in the absence of viral protein synthesis. Products of the β genes, or early genes, include the enzymes necessary for viral replication, such as HSV thymidine kinase, which is targeted by acyclovir and related antiviral drugs, and other regulatory proteins. β genes require functional α gene products for expression. The onset of expression of β genes coincides with a decline in the rate of expression of α genes and an irreversible shutoff of host cellular macromolecular protein synthesis. Structural proteins, such as proteins that form the viral capsid, are usually of the γ, or late, gene class. The γ genes are heterogeneous and are differentiated from β genes by their requirement for viral DNA synthesis for maximal expression. Most glycoproteins are expressed predominantly as late genes. In addition to its regulatory and structural genes, the virus encodes genes that allow initial evasion of the innate host cell response, including gene products that block the interferon pathway. HSV-1 and HSV-2 also express proteins that interfere with adaptive immunity, as exemplified by an immediate-early protein, ICP47, that mediates the downregulation of major histocompatibility complex class I molecules, which are required for recognition of HSV-infected cells by HSV-specific $CD8^+$ T cells [8,9].

Replication of viral DNA occurs in the nucleus of the cell. Assembly of the virus begins with formation of nucleocapsids in the nucleus, followed by egress across the nuclear membrane and envelopment at cytoplasmic locations. Virus particles are transported to the plasma membrane, where progeny virions are released. HSV glycoproteins have been designated as B, C, D, E, G, H, I, L, and M [4,5]. Glycoproteins B, D, and H (gB, gD, and gH) are required for infectivity and are targets of neutralizing antibodies against HSV; glycoprotein C (gC) binds to the C3b component of complement; and the glycoprotein E (gE) and glycoprotein I (gI) complex binds to the Fc portion of IgG.

The amino acid sequences of glycoprotein G (gG) produced by HSV-1 and HSV-2 are sufficiently different to elicit antibody responses that are specific for each virus type. The fact that the antibody response to the two G molecules exhibits minimal cross-reactivity has provided the basis for serologic methods that can be used to detect recent or past HSV-2 infection in individuals who have also been infected with HSV-1 [10–13]. The close antigenic relatedness between HSV-1 and HSV-2 interferes with the serologic diagnosis of these infections when using standard serologic assays, which do not distinguish between individuals who have had past infection with HSV-1 only, infection with HSV-2 only, or dual infection. Commercial type-specific tests based on gG must be used for diagnosis of HSV-2 infection [12]. Clinicians should be knowledgeable regarding the type of testing performed by the laboratory to interpret results correctly.

## LATENCY AND REACTIVATION

All of the herpesviruses have a characteristic ability to establish latency, to persist in this latent state for various intervals of time, and to reactivate, causing virus excretion at mucosal or other sites. After primary infection, the HSV genome persists in sensory ganglion neurons for the lifetime of the individual. The biologic phenomenon of latency has been recognized and described since the beginning of the 20th century. In 1905, Cushing [14] observed that patients treated for trigeminal neuralgia by sectioning a branch of the trigeminal nerve developed herpetic lesions in areas innervated by the sectioned branch. This specific association of HSV with the trigeminal ganglion was suggested by Goodpasture [15]. Past observations have shown that microvascular surgery of the trigeminal nerve tract to alleviate pain associated with tic douloureux resulted in recurrent lesions in more than 90% of seropositive individuals [16,17].

Accumulated experience in animal models and from clinical observations suggests that inoculation of virus at the portal of entry, usually oral or genital mucosal tissue, results in infection of sensory nerve endings, and the virus is transported to the dorsal root ganglia [18]. Replication at the site of inoculation enhances access of the virus to ganglia, but is usually not associated with signs of mucocutaneous disease. Only a fraction of new infections with HSV-1 and HSV-2 cause clinically recognizable disease. When reactivation is triggered at oral or genital sites, virus is transported back down axons to mucocutaneous sites where replication and shedding of infectious HSV occurs.

Recognizing that excretion of infectious virus during reactivation is not usually associated with clinical signs of recurrent herpes lesions is essential for understanding the transmission of HSV to newborns. Clinically silent reactivations are much more common than recurrent lesions. Reactivation with or without symptoms occurs in the healthy host in the presence of HSV-specific humoral and cell-mediated immunity. Reactivation seems to be spontaneous, although symptomatic recurrences have been associated with physical or emotional stress, exposure to ultraviolet light, or tissue damage; immunosuppression is associated with an increased susceptibility to symptomatic HSV infections when reactivation occurs. Persistence of viral DNA has been documented in neuronal tissue of animal models and humans [4,19–21]. Because the latent virus does not multiply, it is not susceptible to drugs such as acyclovir that affect DNA synthesis and cannot be eradicated from the infected host. Understanding of the mechanisms by which HSV establishes a latent state and persists in this form remains limited.

## EPIDEMIOLOGY AND TRANSMISSION

Transmission of HSV most often occurs as a consequence of intimate person-to-person contact. Virus must come in contact with mucosal surfaces or abraded skin for infection to be initiated.

The usual mode of HSV-1 transmission is through direct contact of a susceptible individual with infected secretions, although transfer in respiratory droplets is possible. Acquisition often occurs during childhood. Primary HSV-1 infection in a young child is usually asymptomatic, but clinical illness is associated with HSV gingivostomatitis. Primary infection in young adults has been associated with pharyngitis only or with a mononucleosis-like syndrome. Seroprevalence studies have shown that acquisition of HSV-1 infection, similar to that of other herpesvirus infections, is related to socioeconomic factors [22,23]. Antibodies, indicative of past infection, are found early in life among individuals of lower socioeconomic groups, presumably reflecting the crowded living conditions that provide a greater opportunity for direct contact with infected individuals. By the end of the 1st decade of life, 75% to 90% of individuals from lower socioeconomic populations develop antibodies to HSV-1 [24–26]. In middle and upper middle socioeconomic groups, 30% to 40% of individuals are seropositive by the middle of the 2nd decade of life.

A change in seroprevalence rates of HSV-1 has been recognized in the past few decades, which reflects a delay in acquisition of infection until later in life. An increase in the reported number of cases of genital herpes caused by HSV-2 may be related to a lower prevalence of prior HSV-1 infection in young adults. These individuals would not have the partial protection against HSV-2 infection that is probably conferred by cross-reactive HSV-1 immunity. In recent years, an increasing number of cases of genital HSV have been found to be caused by HSV-1 [27,28].

Because infection with HSV-2 is usually acquired through sexual contact, antibodies to this virus are rarely found until the age of onset of sexual activity [25]. A progressive increase in infection rates with HSV-2 in all populations begins in adolescence. In earlier studies, the precise seroprevalence of antibodies to HSV-2 had been difficult to determine because of cross-reactivity with HSV-1 antigens. During the late 1980s, seroepidemiologic studies performed using type-specific antigen for HSV-2 (glycoprotein G-2) identified this virus in approximately 25% to 35% of middle-class women in several geographic areas of the United States [11,29–31]. Based on national health surveys, the seroprevalence of HSV-2 in the United States from 1988–1994 was 21.9% for individuals 12 years and older [31]. Among individuals with serologic evidence of infection, less than 10% had a history of genital herpes symptoms. This seroprevalence represented a 30% increase compared with data collected from 1976–1980. There is evidence, however, from more recent national health surveys (1999–2004) that this trend of increasing HSV-2 seroprevalence is reversing [28]. HSV seroprevalence is highly variable and depends on geographic region, sex, age, race, and high-risk behaviors [32].

The molecular epidemiology of HSV infections can be determined by restriction enzyme analysis of viral DNA or polymerase chain reaction (PCR) and sequencing of regions of the HSV genome obtained from infected individuals. Viruses have essentially identical genetic profiles when they are from the same host or are epidemiologically related [33]. In a few circumstances, it has been shown, however, that superinfection or exogenous

reinfection with a new strain of HSV is possible. Such occurrences are uncommon in a nonimmunocompromised host with recurrent genital HSV infection [33–35]. Differences in the genetic sequence of viral DNAs indicating exogenous infections are more common in immunocompromised individuals who are exposed to different HSVs, such as patients with acquired immunodeficiency syndrome (AIDS).

## MATERNAL INFECTION

Infection with HSV-2, which reactivates and is shed at genital sites, is common in pregnant women. Using assays to detect type-specific antibodies to HSV-2, seroepidemiologic investigations have shown that approximately one in five pregnant women has had HSV-2 infection [23,30,36–40]. Given the capacity of HSV to establish latency, the presence of antibodies is a marker of persistent infection of the host with the virus. The incidence of infection in women of upper socioeconomic class was 30% or greater in three large studies [38,40,41]. These investigations have shown that most women with serologic evidence of HSV-2 infection have no history of symptomatic primary or recurrent disease. New HSV-2 infections are acquired during pregnancy with a frequency that is comparable to seroconversion rates among nonpregnant women, and these infections usually occur without clinical signs or symptoms [37–41].

Evaluation of pregnant women and their partners has shown that women can remain susceptible to HSV-2 despite prolonged sexual contact with a partner who has known genital herpes [39]. One in 10 women in this study were found to be at unsuspected risk for acquiring HSV-2 infection during pregnancy as a result of contact with a partner whose HSV-2 infection was asymptomatic. Most maternal infections are clinically silent during gestation. Infection during gestation may manifest in several clinical syndromes, however.

Widely disseminated disease is an uncommon problem encountered with HSV infections during pregnancy. As first reported by Flewett and coworkers [42] in 1969 and by others [43,44] subsequently, infection has been documented to involve multiple visceral sites in addition to cutaneous ones. In a few cases, dissemination after primary oropharyngeal or genital infection has led to severe manifestations of disease, including necrotizing hepatitis with or without thrombocytopenia, leukopenia, disseminated intravascular coagulopathy, and encephalitis. Although only a few patients have had disseminated infection, the mortality rate for these pregnant women is more than 50%. Fetal deaths were described in more than 50% of cases, although mortality did not correlate with the death of the mother. Surviving fetuses were delivered by cesarean section during the acute illness or at term; none of the surviving fetuses had evidence of neonatal HSV infection.

Earlier studies described an association of maternal primary infection before 20 weeks' gestation [45] with spontaneous abortion in some women. Although the original incidence of spontaneous abortion after a symptomatic primary infection during gestation was thought to be 25%, this estimate was not substantiated by prospective studies and was erroneous because of the small number of women followed. More precise data obtained from a prospective analysis of susceptible women showed that 2% or more acquired infection, but that acquisition of infection was not associated with a risk of spontaneous abortion [46]. With the exception of rare case reports, primary infection that develops later in gestation is not generally associated with premature rupture of membranes or premature termination of pregnancy [47].

Localized genital infection, whether it is associated with lesions or remains asymptomatic, is the most common form of HSV infection during pregnancy. Overall, prospective investigations using cytologic and virologic screening indicate that genital herpes occurs with a frequency of about 1% in women tested at any time during gestation [38,46]. Most genital infections were classified as recurrent when HSV-2–specific serologic testing was done. Transmission of infection to the infant is most frequently related to the actual shedding of virus at the time of delivery. Because HSV infection of the infant is usually the consequence of contact with infected maternal genital secretions at the time of delivery, the incidence of viral excretion at this time point has been of particular interest. The reported incidence of viral excretion at delivery is 0.01% to 0.39% for all women, regardless of their history of genital herpes [38,41].

Several prospective studies have evaluated the frequency and nature of viral shedding in pregnant women with a known history of genital herpes. These women represent a subset of the population of women with HSV-2 infection because they had a characteristic genital lesion from which virus was isolated. In a predominantly white, middle-class population, symptomatic recurrent infection occurred during pregnancy in 84% of pregnant women with a history of symptomatic disease [48]. Viral shedding from the cervix occurred in only 0.56% of symptomatic infections and 0.66% of asymptomatic infections. These data are similar to data obtained from other populations [29]. The incidence of cervical shedding in asymptomatic pregnant women has been reported to range from 0.2% to 7.4%, depending on the numbers of cultures that were obtained between symptomatic episodes. Overall, these data indicate that the frequency of cervical shedding is low, which may reduce the risk of transmission of virus to the infant when the infection is recurrent. The frequency of shedding does not seem to vary by trimester during gestation. No increased incidence of premature onset of labor was apparent in these prospective studies of women with known HSV-2 infection.

Most infants who develop neonatal disease are born to women who are completely asymptomatic for genital HSV infection during the pregnancy and at the time of delivery. These women usually have neither a past history of genital herpes nor a sexual partner reporting a genital vesicular rash and account for 60% to 80% of all women whose infants become infected [49,50].

## FACTORS INFLUENCING TRANSMISSION OF INFECTION TO THE FETUS

The development of serologic assays that distinguish antibodies to HSV-1 from antibodies elicited by HSV-2 infection allowed an accurate analysis of risks related to perinatal

transmission of HSV [10–13]. The category of maternal genital infection at the time of delivery influences the frequency of neonatal acquisition of infection. Maternal infections are classified as caused by HSV-1 or HSV-2 and as newly acquired or recurrent. These categories of maternal infection status are based on laboratory criteria and are independent of clinical signs.

Women with recurrent infections are those who have preexisting antibodies to the virus type that is isolated from the genital tract, which, until more recently, is usually HSV-2. Most women classified as having recurrent infection have no history of symptomatic genital herpes. Infections that are newly acquired, which have been referred to as first-episode infections, are categorized further as primary or first-episode nonprimary based on type-specific serologic testing. This differentiation is made whether clinical signs are present or not. Primary infections are infections in which the mother is experiencing a new infection with HSV-1 or HSV-2 and has not already been infected with the other virus type. These mothers are seronegative for any HSV antibodies (i.e., negative for HSV-1 or HSV-2) at the onset of infection. Nonprimary infections are infections in which the mother has a new infection with one virus type, usually HSV-2, but has antibodies to the other virus type, usually HSV-1, because of an infection that was acquired previously.

As transmission has been studied using type-specific serologic methods, it has become apparent that attempts to distinguish primary and recurrent disease by clinical criteria are unreliable. Serologic classification is an important advance because many "new" genital herpes infections in pregnancy represent the first symptomatic episode of infection acquired at some time in the past. In one study designed to evaluate acyclovir therapy, pregnant women who were thought to have recent acquisition of HSV-2 based on symptoms all had been infected previously. These women were experiencing genital symptoms, caused by reactivation of latent virus, for the first time [44]. A hierarchy of risk of transmission has emerged using laboratory tools to classify maternal infection. Infants born to mothers who have true primary infection at the time of delivery are at highest risk, with transmission rates of 50% or greater [46,49]. Infants born to mothers with new infections that are first episode but nonprimary seem to be at lower risk; transmission rates are estimated to be about 30%. The lowest risk of neonatal acquisition occurs when the mother has active infection caused by shedding of virus acquired before the pregnancy or at stages of gestation before the onset of labor. The estimated attack rate for neonatal herpes among these infants is less than 2%. This estimate is reliable because it is based on the cumulative experience from large, prospective studies of pregnant women in which viral shedding was evaluated at delivery, regardless of the mother's history of genital herpes or contact with a partner with suspected or documented genital herpes.

The higher risk of transmission to the infant when the mother has a new infection can be attributed to differences in the quantity and duration of viral shedding in the mother and in the transfer of passive antibodies from the mother to the infant before delivery. Primary infection is associated with larger quantities of virus replication in the genital tract (>$10^6$ viral particles per 0.2 mL of inoculum) and a period of viral excretion that may persist for an average of 3 weeks [51]. Many women with new infections have no symptoms, but shed virus in high titers. In some mothers, these infections cause signs of systemic illness, including fever, malaise, myalgias, dysuria, and headache. Viremia during primary HSV infection in women is common and is associated with systemic symptoms [52]. In a small percentage of cases, significant complications, such as urinary retention and aseptic meningitis, occur.

In contrast, virus is shed for an average of only 2 to 5 days and at lower concentrations (approximately $10^2$ to $10^3$ viral particles per 0.2 mL of inoculum) in women with symptomatic recurrent genital infections. Asymptomatic reactivation is also associated with short periods of viral replication, often less than 24 to 48 hours. One of the most important observations about HSV infections that has emerged from the evaluation of pregnant women is that new HSV-1 and HSV-2 infections often occur without any of the manifestations that were originally described as the classic findings in primary and recurrent genital herpes.

In parallel with the classification of maternal infection, the mother's antibody status to HSV at delivery seems to be an additional factor that influences the likelihood of transmission and probably affects the clinical course of neonatal herpes. Transplacental maternal neutralizing antibodies seem to have a protective, or at least an ameliorative, effect on acquisition of infection for infants inadvertently exposed to virus [53]. Maternal primary infection late in gestation may not result in significant passage of maternal antibodies across the placenta to the fetus. Based on available evidence, the highest risk of transmission from mothers with newly acquired genital herpes is observed when the infant is born before the transfer of passive antibodies to HSV-1 or HSV-2, when the infant is exposed at delivery or within the first few days of life [46,54].

The duration of ruptured membranes has also been described as an indicator of risk for acquisition of neonatal infection. Observations of a small cohort of women with symptomatic genital herpes indicated that prolonged rupture of membranes (>6 hours) increased the risk of acquisition of virus, perhaps as a consequence of ascending infection from the cervix [45]. It is recommended that women with active genital lesions at the time of onset of labor be delivered by cesarean section [55]. One study found that cesarean section significantly reduced the rate of HSV infection in infants born to women from whom HSV was isolated at the time of delivery (1.2% versus 7.7%, $P = .047$) [56]. This effect of cesarean delivery was established by postdelivery analysis of data on viral shedding at delivery for a large cohort of pregnant women. In the absence of a reliable rapid test for HSV in the birth canal, it is difficult at this time to apply this information in clinical practice. The benefit of cesarean section beyond 6 hours of ruptured membranes has not been evaluated. Although some protection may be expected, infection of the newborn has occurred despite delivery by cesarean section [50,57].

Certain forms of medical intervention during labor and delivery may increase the risk of neonatal herpes if the mother has active shedding of the virus, although in most

instances, viral shedding is not suspected clinically. Fetal scalp monitors can be a site of viral entry through skin [56,58,59]. The benefits and risks of these devices should be considered for women with a history of recurrent genital HSV infections. Because most women with genital infections caused by HSV are asymptomatic during labor and have no history of genital herpes, it is usually impossible to make this assessment.

## INCIDENCE OF NEWBORN INFECTION

A progressive increase in the number of cases of neonatal HSV infection to a rate of approximately 1 in 1500 deliveries was reported in King County, Washington, during the period from 1966–1983, when adult infection rates were also increasing [60]. Overall, the United States, with approximately 4 million deliveries each year, has an estimated 11 to 33 cases of neonatal infection per 100,000 live births. This estimate has been confirmed by a review of comprehensive hospital discharge data recorded in California for the years 1985, 1990, and 1995. The diagnosis of HSV infection in infants 6 weeks or younger was made in 11.7, 11.3, and 11.4 infants per 100,000 live births in each of these years [61]. A more recent study from California, using similar methods of analysis of hospital discharge data, found the incidence of HSV infection in infants to be 12.1 per 100,000 live births per year with no change from 1995–2003 [62]. The use of ICD-9 discharge diagnosis coding seems to be a sensitive but relatively nonspecific method for identifying neonatal HSV infections [63].

In studies in which maternal serologic status during pregnancy and virologic status at the time of delivery are evaluated prospectively, the rate of transmission leading to neonatal HSV infection ranges from 12 to 54 newborn infections per 100,000 births. Higher rates of transmission are seen in infants born to seronegative mothers and mothers infected with HSV-1 [56]. Based on seroprevalence studies, the highest risk HSV transmission would be expected to occur in infants born to non-Hispanic white mothers, whose HSV seroprevalence is the lowest [23]. Neonatal HSV infection occurs far less frequently than might be expected given the high prevalence of genital HSV infections in women of childbearing age in the United States. Some countries do not report a significant number of cases of neonatal HSV infection despite a similar high prevalence of antibodies to HSV-2 in women. In the United Kingdom, genital herpes infection is relatively common, but very few cases of neonatal HSV infection are recognized. Neonatal HSV infection in the Netherlands occurs in only 2.4 of 100,000 newborns [64].

Although underreporting of cases may explain some differences between countries, unidentified factors may account for these differences. The interpretation of incidence data must also include the potential for postnatal acquisition of HSV infection. Not all cases of neonatal infection are the consequence of intrapartum contact with infected maternal genital secretions, which alters the overall estimate of delivery-associated infection. The prevalence of neonatal HSV infection relative to serious bacterial infections in hospitalized neonates was evaluated more recently in a retrospective study and found to be 0.2% compared with 0.4% and 4.5% for infants with bacterial meningitis and serious bacterial infections [65].

## TIMES OF TRANSMISSION OF INFECTION

HSV infection of the newborn can be acquired in utero, intrapartum, or postnatally. The mother is the most common source of infection for the first two of these three routes of transmission of infection. With regard to postnatal acquisition of HSV infection, the mother can be a source of infection from a genital or nongenital site. Other contacts or environmental sources of virus can lead to infection of the infant. A maternal source is suspected when maternal herpetic lesions are discovered shortly after the birth of the infant or when the infant's illness is caused by HSV-2. Although intrapartum transmission accounts for 85% to 95% of cases, in utero and postnatal infection must be recognized for public health and prognostic purposes.

In utero transmission is rare [66–69]. Although it was originally presumed that in utero acquisition of infection resulted in a totally normal infant or premature termination of gestation [45], it has become apparent that intrauterine acquisition of infection can lead to the clinical signs of congenital infection. When using stringent diagnostic criteria, more than 30 infants with symptomatic congenital disease have been described in the literature. These criteria include identification of infected infants with lesions present at birth; virologic confirmation of HSV; and exclusion of other infectious agents whose pathogenesis mimics the clinical findings of HSV infections, such as congenital cytomegalovirus infection, rubella, syphilis, or toxoplasmosis. Virologic diagnosis is a necessary criterion because no standard method for detection of IgM antibodies is available, and infected infants often fail to produce IgM antibodies detectable by research methods [54,70]. The manifestations of disease in this group of children range from the presence of skin vesicles at the time of delivery to the most severe neurologic abnormalities [50,68].

In utero infection can result from transplacental or ascending infection. The placenta can show evidence of necrosis and inclusions in the trophoblasts, which suggests a transplacental route of infection [71]. The situation can result in an infant who has hydranencephaly at the time of birth, or it may be associated with spontaneous abortion and intrauterine HSV viremia. Virus has been isolated from the products of conception under such circumstances. Histopathologic evidence of chorioamnionitis suggests ascending infection as an alternative route for in utero infection [72]. Risk factors associated with intrauterine transmission are unknown. Primary and recurrent maternal infections can result in infection of the fetus in utero. HSV DNA has been detected in the amniotic fluid of two women experiencing a first-episode nonprimary infection and in one woman during a symptomatic recurrent infection. All three infants were healthy at birth and showed no clinical or serologic evidence of HSV infection during follow-up [73].

The second and most common route of infection is intrapartum contact of the fetus with infected maternal genital secretions. Intrapartum transmission is favored by delivery of the infant to a mother with newly acquired infection.

Postnatal acquisition is the third route of transmission. Postnatal transmission of HSV-1 has been suggested as an increasing risk. Data from the National Institute of Allergy and Infectious Diseases (NIAID) Collaborative Antiviral Study Group (CASG) indicate that the frequency of infants with neonatal HSV-1 infection ranges from approximately 25% to 35% [50,74]. An increase in HSV-1 genital infections in the United States may account for some neonatal HSV-1 infections; however, some infants acquire nongenital HSV-1 from the mother after birth or from nonmaternal sources. Relatives and hospital personnel with orolabial herpes may be a reservoir of virus for infection of the newborn.

The documentation of postnatal transmission of HSV-1 has focused attention on sources of virus [75–79]. Postpartum transmission from mother to child has been reported as a consequence of nursing on an infected breast [80]. Transmission from fathers and grandparents has also been documented [79]. When the infant's mother has not had HSV infection, the infant may be inoculated with the virus from a nonmaternal contact in the absence of any possible protection from maternally derived passive antibodies. Because of the prevalence of HSV-1 infection in the general population, many individuals have intermittent episodes of asymptomatic excretion of the virus from the oropharynx and can provide a source of infection for the newborn. The occurrence of herpes labialis, commonly referred to as fever blisters or cold sores, has ranged from 16% to 46% in various groups of adults [81].

Population studies conducted in two hospitals indicated that 15% to 34% of hospital personnel had a history of nongenital herpetic lesions [81,82]. In both hospitals surveyed, at least 1 in 100 individuals documented a recurrent cold sore each week. As is true of genital herpes, many individuals have HSV-1 infection with no clinical symptoms at the time of acquisition or during episodes of reactivation and shedding of infectious virus in oropharyngeal secretions. Prospective virologic monitoring of hospital staff increased the frequency with which infection was detected by twofold; however, no cases of neonatal HSV infection were documented in these nurseries.

The risk of nosocomial infection in the hospital environment is a concern. Identification by restriction endonuclease or sequence analysis of virus recovered from an index case and a nursery contact leaves little doubt about the possibility of spread of virus in a high-risk nursery population [76,78]. The possible vectors for nosocomial transmission have not been defined. Whether personnel with herpes labialis should avoid working in the nursery while lesions are active remains a matter of debate. No cases of transmission of HSV from personnel to infants have been documented. Meticulous hand-washing procedures and continuing education of personnel in newborn nurseries can contribute to the low frequency of HSV transmission in this environment. Herpetic whitlow in a health care provider should preclude direct patient contact, regardless of the nursing unit. Because more infants are born to seronegative women now, our nursery practice is to exclude personnel with active herpes labialis from direct patient care activities until the lesion is crusted.

Because most mothers have antibodies to HSV, and these antibodies are transferred to their infants, exposures to the virus in the newborn period often may not result in neonatal disease. If the mother was seronegative, nosocomial exposure may pose a more significant risk to the infant, however.

## IMMUNOLOGIC RESPONSE

The host response of the newborn to HSV is impaired compared with older children and adults [54,70,83–87]. There is no evidence for differences in virulence of particular HSV strains. The severity of the manifestations of HSV-1 and HSV-2 infections in the newborn can be attributed to immunologic factors. Relevant issues are protection by transplacental antibodies, the innate immune response of the exposed infant, and the acquisition of adaptive immunity by the infected newborn.

Passive antibodies to HSV influence the acquisition of infection and its severity and clinical signs [40,49,54,70]. Transplacentally acquired antibodies from the mother are not totally protective against newborn infection, but transplacentally acquired neutralizing antibodies correlate with a lower attack rate in exposed newborns [49,53,54]. Although the absence of any detectable antibodies has been associated with dissemination, the presence of antibodies at the time that clinical signs appear does not predict the subsequent outcome [50,70]. The most important example of the failure of passive antibodies to alter progression is the occurrence of encephalitis in untreated infants whose initial symptoms were limited to cutaneous lesions.

Most infected newborns eventually produce IgM antibodies, but the interval to detection is prolonged, requiring at least 2 to 4 weeks [54]. These antibodies increase rapidly during the first 2 to 3 months, but may be detectable for 1 year after infection. The quantity of neutralizing antibodies and antibodies that mediate antibody-dependent cellular cytotoxicity in infants with disseminated infection is lower than in infants with more limited disease [54,86]. Humoral antibody responses to specific viral proteins, especially glycoproteins, have been evaluated by assays for antibodies to gG and by immunoblot [10,70]. Immunoblot studies indicate that the severity of infection correlates directly with the number of antibody bands to defined polypeptides. Children with a more limited infection, such as infection of the skin, eye, or mouth, have fewer antibody bands compared with children with disseminated disease.

A vigorous antibody response to the ICP4 $\alpha$ gene product, which is responsible for initiating viral replication, has been correlated with poor long-term neurologic outcome, suggesting that these antibodies reflect the extent of viral replication. A regression analysis that compared neurologic impairment with the quantity of antibodies to ICP4 identified the child at risk for severe neurologic impairment [70].

Adaptive cellular immunity is a crucial component of the host response to primary herpetic infection. Newborns with HSV infections have a delayed T-lymphocyte proliferative response compared with older individuals [54,83,84]. Most infants have no detectable T-lymphocyte responses to HSV when evaluated 2 to 4 weeks after the onset of clinical symptoms [54]. The delayed T-lymphocyte response to

viral antigens in infants whose initial disease is localized to the skin, eye, or mouth may be an important determinant of the frequent progression to more severe disease in infants [54,83]. The importance of interferon-γ may be related to its effect on the induction of innate immune mechanisms, such as natural killer cell responses [85]. Other mechanisms of the innate immune system of the newborn that may be deficient in controlling HSV include other nonspecific cytokine responses and complement-mediated effects. T lymphocytes from infected infants have decreased interferon-γ production during the 1st month of life. This defect can be predicted to limit the clonal expansion of helper and cytotoxic T lymphocytes specific for herpes viral antigens, allowing more extensive and prolonged viral replication.

Antibody-dependent cell-mediated cytotoxicity has been shown to be an important component of adaptive immunity to viral infection [86]. Lymphocytes, monocytes, macrophages, or polymorphonuclear leukocytes and antibodies and complement lyse HSV-infected cells in vitro [88]. However, newborns appear to have fewer effector lymphocytes than older individuals do. The immaturity of neonatal monocytes and macrophage function against HSV infection has been demonstrated in vitro and in animal models [89,90]. Additional information regarding the immune response to HSV is provided in Chapter 4.

# NEONATAL INFECTON

## PATHOGENESIS AND PATHOLOGY

After direct exposure, replication of HSV is presumed to occur at the portal of entry, which is probably the mucous membranes of the mouth or eye, or at sites where the skin has been damaged. Factors that determine whether the infection causes symptoms at the site of inoculation or disseminates to other organs are poorly understood. Sites of replication during the incubation period have not been well defined, but the virus evades the host response during this early stage, probably by mechanisms such as interfering with expression of the interferon response genes and blocking cell-mediated immune recognition of viral peptides by preventing major histocompatibility complex class I molecules from reaching the surface of infected cells.

Intraneuronal transmission of viral particles may provide a privileged site that is relatively inaccessible to circulating humoral and cell-mediated defense mechanisms, facilitating the pathogenesis of encephalitis. Transplacental maternal antibodies may be less effective under such circumstances. Disseminated infection seems to be the consequence of viremia. HSV DNA has been detected in peripheral blood mononuclear cells, even in infants who seem to have localized infection [91]. Extensive cell-to-cell spread could explain primary HSV pneumonia after aspiration of infected secretions.

After the virus has adsorbed to cell membranes, and penetration has occurred, viral replication proceeds, leading to release of progeny virus and cell death. The synthesis of cellular DNA and protein ceases as large quantities of HSV are produced. Many infants with disseminated HSV infection have high viral loads and higher concentrations of inflammatory cytokines compared with infants with central nervous system (CNS) infection alone or skin, eye, or mouth disease [92]. Uncontrolled host immune responses may lead to the development of multiple organ dysfunction. Cell death in critical organs of the newborn, such as the brain, results in devastating consequences, as reflected by the long-term morbidity of herpes encephalitis. Cellular swelling, hemorrhagic necrosis, development of intranuclear inclusions, and cytolysis all result from the replication process and ensuing inflammatory response. Small, punctate, yellow-to-gray areas of focal necrosis are the most prominent gross lesions in infected organs. When infected tissue is examined by microscopy, there is extensive evidence of hemorrhagic necrosis, clumping of nuclear chromatin, dissolution of the nucleolus, cell fusion with formation of multinucleate giant cells, and, ultimately, a lymphocytic inflammatory response [93]. Irreversible organ damage results from ischemia and direct viral destruction of cells.

## CLINICAL MANIFESTATIONS

Pediatricians must be prepared to consider the diagnosis of neonatal herpes in infants who have clinical signs consistent with the disease regardless of the maternal history or genital herpes. Only about 30% of mothers whose infants develop neonatal herpes have had symptomatic genital herpes or sexual contact with a partner who has recognized HSV infection during or before the pregnancy.

The clinical presentation of infants with neonatal HSV infection depends on the initial site and extent of viral replication. In contrast to human cytomegalovirus, neonatal infections caused by HSV-1 and HSV-2 are almost invariably symptomatic. Case reports of asymptomatic infection in the newborn exist, but are uncommon, and long-term follow-up of these children to document absence of subtle disease or sequelae was not described.

Classification of newborns with HSV infection is used for prognostic and therapeutic considerations [94]. Historically, infants with neonatal HSV infection were classified as having localized or disseminated disease, with the former group being subdivided into infants with skin, eye, or mouth disease versus infants with CNS infection. This classification system understates the significant differences in outcome within each category, however [95]. In a revised classification scheme, infants who are infected intrapartum or postnatally are divided into three groups: disease localized to the skin, eye, or mouth; encephalitis, with or without skin, eye, or mouth involvement; and disseminated infection that involves multiple organs, including the CNS, lung, liver, adrenals, skin, eye, or mouth. A few infants with intrauterine infection constitute a fourth category.

Knowledge of the patterns of clinical disease caused by HSV-1 and HSV-2 in the newborn is based on prospectively acquired data obtained through the NIAID CASG. These analyses have employed uniform case record forms from one study interval to the next. Of 186 infants enrolled in the NIAID CASG studies of neonatal herpesvirus infections from 1981–1997, 34% were classified with skin, eye, or mouth disease; 34% were classified with CNS disease; and 32% were classified with disseminated infection [74]. This analysis of the natural history of neonatal herpes infections likely underestimates

the proportion of infants who present with skin, eye, or mouth disease. Patients with CNS or disseminated HSV infection were disproportionately enrolled in a high-dose acyclovir study conducted from 1989–1997. The presentation and outcome of infection, including the effect of antiviral therapy on prognosis, vary significantly according to the clinical categories [96]. Table 26–1 summarizes disease classification and outcome of 291 infants with neonatal HSV infections enrolled in NIAID CASG protocols.

## Intrauterine Infection

Intrauterine infection is rare. The manifestations are seen in approximately 3 of every 100 infected infants [66]. When infection occurs in utero, severe disease follows acquisition of infection at virtually any time during gestation. In the most severely affected group of infants, evidence of infection is apparent at birth and is characterized by a triad of findings: skin vesicles or scarring, eye damage, and severe manifestations of microcephaly or hydranencephaly. CNS damage is caused by intrauterine encephalitis. Infants do not have evidence of embryopathy, such as cardiac malformations. Often, chorioretinitis combined with other eye findings, such as keratoconjunctivitis, is a component of the clinical presentation.

Serial ultrasound examination of the mothers of infants infected in utero has shown the presence of hydranencephaly, but cases are seldom diagnosed before delivery. Chorioretinitis alone should alert the pediatrician to the possibility of this diagnosis, although it is a common sign for other congenital infections. A few infants have been described who have signs of HSV infection at birth after prolonged rupture of membranes. These infants may have no other findings of invasive multiorgan involvement—no chorioretinitis, encephalitis, or evidence of other diseased organs—and can be expected to respond to antiviral therapy. Antiviral therapy is ineffective for infants who are born with hydranencephaly. Intrauterine HSV infection has been reported as a cause of hydrops fetalis [97].

## Disseminated Infection

Infants whose initial diagnosis is disseminated herpes have the worst prognosis for mortality. Many of these infants are born to mothers who are experiencing a new HSV-1 or HSV-2 infection and may lack any passively acquired antibodies against the infecting virus type [10,49,98]. Infants with disseminated infection have signs of illness within the 1st week of life, although the diagnosis may be delayed until the 2nd week. The onset of symptoms may occur less than 24 hours after birth, but most infants appear well at delivery. The short incubation period of disseminated herpes reflects an acute viremia, which allows transport of the virus to all organs; the principal organs involved are the adrenals and the liver, resulting in fulminant hepatitis in some cases [94,99–102]. Viremia is associated with infection of circulating mononuclear cells in these infants [91,99,101,103,104].

Infection can affect multiple organs, including the CNS, larynx, trachea, lungs, esophagus, stomach, lower gastrointestinal tract, spleen, kidneys, pancreas, and heart. Initial signs and symptoms are irritability, seizures, respiratory distress, jaundice, coagulopathy, and shock. The characteristic vesicular exanthem is usually not present when the symptoms begin. Untreated infants may develop cutaneous lesions resulting from viremia. More than one third of children with disseminated infection do not

develop skin vesicles during the course of their illness [50,74,99]. Disseminated infections caused by HSV-1 and HSV-2 are indistinguishable by clinical criteria.

The diagnosis of disseminated neonatal herpes is exceedingly difficult because the clinical signs are often vague and nonspecific, mimicking signs of neonatal enteroviral disease or bacterial sepsis. The diagnosis of disseminated herpes should be pursued by obtaining specimens of oropharyngeal and respiratory secretions and a rectal swab to be tested by viral culture and by PCR testing if a qualified reference laboratory is available. Direct immunofluorescent methods are useful for rapid diagnosis of herpesvirus-infected cells in skin lesion specimens, but must not be used to test oropharyngeal or other secretions. If discrete lesions are unavailable for obtaining infected cells, the virus can also be detected in the peripheral blood of some infants by viral culture or PCR, but confirmation of viremia is unnecessary for clinical management.

Evaluation of the extent of dissemination is imperative to provide appropriate supportive interventions early in the clinical course. Infants should be assessed for hypoxemia, acidosis, hyponatremia, abnormal hepatic enzyme levels, direct hyperbilirubinemia, neutropenia, thrombocytopenia, and bleeding diathesis. Chest radiographs should be obtained. Depending on signs and whether the infant is stable enough, abdominal radiography, electroencephalography, and computed tomography (CT) or magnetic resonance imaging (MRI) of the head should be obtained to determine further the extent of disease. The radiographic picture of HSV lung disease is characterized by a diffuse, interstitial pattern, which progresses to a hemorrhagic pneumonitis and, rarely, a significant pleural effusion [105]. Frequently, necrotizing enterocolitis with pneumatosis intestinalis can be detected when gastrointestinal disease is present. Meningoencephalitis seems to be a common component of disseminated infection, occurring in about 60% to 75% of children. Usual examinations of cerebrospinal fluid (CSF), including viral culture and PCR, should be performed along with noninvasive neurodiagnostic tests to assess the extent of brain disease.

The mortality rate for disseminated HSV in the absence of therapy exceeds 80%, and many survivors are impaired. The most common causes of death of infants with disseminated disease are intravascular coagulopathy or HSV pneumonitis. Premature infants seem to at particularly high risk for disseminated disease with pneumonitis and have a high mortality rate, even with appropriate antiviral therapy [106]. There is evidence that the long-term neurologic outcome is better for infants who survive disseminated HSV-1 involving the CNS than for infants who are infected with HSV-2 [96,107].

## Encephalitis

Almost one third of all infants with neonatal HSV infection have encephalitis only as the initial manifestation of disease [96,108]. These infants have clinical manifestations distinct from infants who have CNS infection associated with disseminated HSV. The pathogenesis of these two forms of brain infection is probably different. The virus is likely to reach brain parenchyma by a hematogenous route in infants with disseminated infection, resulting in multiple areas of cortical hemorrhagic necrosis. In contrast, neonates who present with only encephalitis are likely to develop brain disease because of retrograde axonal transport of the virus to the CNS.

The evidence for this hypothesis is twofold. First, newborns with disseminated disease have documented viremia. Second, infants with encephalitis are more likely to have received transplacental neutralizing antibodies from their mothers, which may allow only intraneuronal transmission of virus to the brain. Infants with localized HSV encephalitis as their initial manifestation of infection usually develop signs more than 1 week after birth, typically presenting in the 2nd or 3rd week, but sometimes not until 4 to 6 weeks. Clinical manifestations of encephalitis include seizures (focal and generalized), fever, lethargy, irritability, tremors, poor feeding, temperature instability, bulging fontanelle, and pyramidal tract signs. Similar signs are observed when disseminated herpesvirus is associated with encephalitis. As in cases of disseminated herpesvirus, many infants with encephalitis do not have skin vesicles when signs of illness begin. Some infants have a history or residual signs of lesions of the skin, eye, or mouth that were not recognized as herpetic. If untreated, infants with encephalitis may develop skin vesicles later in the disease course.

Anticipated findings on CSF examination include a mononuclear cell pleocytosis, moderately low glucose concentrations, and elevated protein. A few infants with CNS infection, proven by brain biopsy done immediately after the onset of seizures, have no abnormalities of CSF, but most infants have some pleocytosis and mild reduction of the glucose level. The hemorrhagic nature of the encephalitis may result in an apparent “bloody tap.” Although initial protein concentrations may be normal or only slightly elevated, infants with localized brain disease usually show progressive increases in protein ($\geq$1000 mg/dL). The importance of CSF examination in all infants is underscored by the finding that even subtle abnormalities have been associated with significant developmental sequelae [94].

Electroencephalography and CT or MRI can be very useful in defining the presence and extent of CNS abnormalities and should be obtained before discharge of all infants with this diagnosis [109,110]. Abnormalities may also be detected by ultrasound examination [110]. Typical abnormalities seen by neuroimaging include localized or multifocal areas of abnormal parenchymal attenuation, atrophy, edema, and hemorrhage involving the temporal, frontal, parietal, and subcortical regions of the brain (Fig. 26–1) [111]. Predominant brainstem involvement is rare but reported [112].

Localized CNS disease is fatal in approximately 50% of infants who are not treated. With rare exceptions, survivors are left with neurologic impairment [94]. The long-term prognosis is poor. Of surviving children, 50% have some degree of psychomotor retardation, often in association with microcephaly, hydranencephaly, porencephalic cysts, spasticity, blindness, chorioretinitis, or learning disabilities. Quantitative PCR methods show a greater amount of HSV-2 DNA in CSF from patients with more extensive

**FIGURE 26–1 Herpes simplex encephalitis.** Computed tomography scan of an infant with herpes simplex virus type 2 infection and severe sequelae.

neurologic impairment [113]. There is evidence that progressive neurologic damage occurs after neonatal encephalitis; many infants have obvious severe sequelae within a few weeks after onset of HSV encephalitis [114,115].

Despite the presumed differences in pathogenesis, neurologic manifestations of disease in children with encephalitis alone are virtually identical to the findings for brain infection in disseminated cases. For infants with encephalitis, approximately 60% develop evidence of a vesicular rash characteristic of HSV infection. A newborn with pleocytosis and elevated protein in the CSF but without a rash can easily be misdiagnosed as having another viral or bacterial infection unless HSV infection is considered.

## Skin, Eye, and Mouth Infections

Infection localized to the skin, eye, or mouth or some combination of these sites seems benign at the onset, but it is associated with a high risk of progression to serious disease. When infection is localized to the skin, the presence of discrete vesicles remains the hallmark of disease (Fig. 26–2). Vesicles occur in 90% of children with skin, eye, or mouth infection. The skin vesicles usually erupt from an erythematous base and are usually 1 to 2 mm in diameter. The formation of new lesions adjacent to the original vesicles is typical, creating a cluster that may coalesce into larger, irregular vesicles. In some cases, the lesions progress to bullae larger than 1 cm in diameter. Clusters of vesicles may appear initially on the presenting part of the body, presumably because of prolonged contact with infectious secretions during birth, or at sites of trauma (e.g., scalp monitor sites). Nevertheless, first herpetic lesions in infants with localized

**FIGURE 26–2 Cutaneous herpes simplex virus infection.** Initial vesicular lesion in a premature infant with herpes simplex type 2 infection.

cutaneous disease have been described on the trunk, extremities, and other sites.

Children with disease localized to the skin, eye, or mouth or some combination of these sites typically have symptoms within the first 7 to 10 days of life. Although discrete vesicles are usually encountered, crops and clusters of vesicles have been described, particularly before antiviral treatment was available or when the cause of the first lesions was not recognized. In these cases, the rash can progress to involve other cutaneous sites, presumably by viremia and hematogenous spread. The scattered vesicles resemble varicella. Although progression is expected without treatment, a few infants have had infection of the skin limited to one or two vesicles, with no further evidence of cutaneous disease. These infants may be identified after the newborn period and should have a careful evaluation because many are likely to have had neurologic disease that was not detected. A zosteriform eruption is another manifestation of herpetic skin disease reported in infants [116].

Infections involving the eye may manifest as keratoconjunctivitis. Ocular infection may be the only site of involvement in a newborn. When localized eye infection is observed in infants who also have microphthalmos and retinal dysplasia, intrauterine acquisition should be suspected, and a thorough neurologic evaluation should be done. Before antiviral therapy was available, persistent ocular disease resulted in chorioretinitis caused by HSV-1 or HSV-2 [117]. Keratoconjunctivitis can progress to chorioretinitis, cataracts, and retinal detachment despite therapy. Cataracts have been detected as a long-term consequence in infants with perinatally acquired HSV infections.

Localized infection of the oropharynx involving the mouth or tongue occurs, but newborns do not develop the classic herpetic gingivostomatitis caused by primary HSV-1 infection in older children. Overall, approximately 10% of patients have evidence of HSV infection of the oropharynx by viral culture. Many of these children did not undergo a thorough oral examination to determine whether the detection of infectious virus in oropharyngeal secretions was associated with lesions.

Long-term neurologic impairment has been encountered in children whose disease seemed to be localized to the skin, eye, or mouth during the newborn period

[50,94,115]. Significant findings include spastic quadriplegia, microcephaly, and blindness. Important questions regarding the pathogenesis of delayed-onset neurologic debility are raised by these clinical observations. Despite normal clinical examination in these children, neurologic impairment became apparent between 6 months and 1 year of age. At this stage of the disease, the clinical presentation may be similar to that associated with congenitally acquired toxoplasmosis or syphilis.

Newborns who have skin lesions invariably experience recurrences for months or years. Continued recurrences are common, particularly when the infecting virus is HSV-2, whether or not antiviral therapy was administered.

Historically, although death was not associated with disease localized to the skin, eye, or mouth, approximately 30% of children eventually developed some evidence of neurologic impairment [50]. Table 26–2 shows morbidity and mortality 12 months after infection by HSV viral type and disease classification in patients enrolled in two studies conducted by the NIAID CASG from 1981–1997. With parenteral acyclovir therapy, virtually all children with HSV-1 and most children with HSV-2 disease of the skin, eye, or mouth who enrolled and who were available for follow-up at 12 months had normal development [74].

### Subclinical Infection

A few cases of apparent subclinical infection with HSV proven by culture isolation of virus in the absence of symptoms have been described [118]. It has been difficult to document such cases in the course of prospective evaluations of several thousand infants from many centers around the United States. Conversely, infants who were exposed to active maternal infection at the time of delivery and who did not develop symptoms have been followed for the 1st year of life and did not have immunologic evidence of subclinical infection [49]. HSV-1 or HSV-2 may be recovered from the infant's oropharyngeal secretions transiently, without representing true infection. Because of the propensity of the newborn to develop severe or life-threatening disease, laboratory evidence of neonatal HSV infection requires careful follow-up for clinical signs and administration of antiviral therapy.

## DIAGNOSIS

### CLINICAL EVALUATION

The clinical diagnosis of neonatal HSV infection is difficult because the appearance of skin vesicles cannot be relied on as an initial component of disease presentation. Enteroviral sepsis is a major differential diagnostic possibility in infants with signs suggesting neonatal HSV. Bacterial infections of newborns can mimic neonatal HSV infection. Skin lesions may resemble lesions seen with bullous or crusted impetigo. Some infants infected by HSV have been described who had concomitant bacterial infections, including group b streptococci, *Staphylococcus aureus*, *Listeria monocytogenes*, and gram-negative bacteria. A positive culture for one of these pathogens does not rule out HSV infection if the clinical suspicion for neonatal herpes infection is present.

Many other disorders of the newborn can be indistinguishable from neonatal HSV infections, including acute respiratory distress syndrome, intraventricular hemorrhage, necrotizing enterocolitis, and various ocular or cutaneous diseases. When vesicles are present, alternative causes of exanthems should be excluded. Other diagnoses include enteroviral infection, varicella-zoster virus infection, and syphilis. Laboratory methods are available to differentiate these causes of cutaneous lesions in the newborn. Cutaneous disorders such as erythema toxicum, neonatal melanosis, acrodermatitis enteropathica, and incontinentia pigmenti often confuse physicians who suspect neonatal HSV infections. HSV lesions can be distinguished rapidly from lesions caused by these diseases using direct immunofluorescence stain of lesion scrapings or other methods for rapid detection of viral proteins and confirmation by viral culture.

HSV encephalitis is a difficult clinical diagnosis to make, particularly because many children with CNS infection do not have a vesicular rash at the time of clinical presentation. Infection of the CNS is suspected in a child who has evidence of acute neurologic deterioration, often associated with the onset of seizure, and in the absence of intraventricular hemorrhage and metabolic causes. PCR to detect viral DNA in CSF has become an important diagnostic method, largely replacing the need for diagnosis by brain biopsy [119]. Infants with localized

encephalitis usually have serial increases in CSF cell counts and protein concentrations and negative bacterial cultures of CSF. Noninvasive neurodiagnostic studies can be used to define sites of involvement.

## LABORATORY ASSESSMENT

The appropriate use of laboratory methods is essential if a timely diagnosis of HSV infection is to be achieved. Virus isolation remains the definitive diagnostic method. If skin lesions are present, a swab of skin vesicles, done vigorously enough to obtain cells from the base of the lesion, should be made and transferred in appropriate virus transport media to a diagnostic virology laboratory. Rapid diagnosis should be attempted by preparing material from skin lesion scrapings for direct immunofluorescence testing to detect the presence of virus-infected cells or for testing by enzyme immunoassays for viral proteins. Because of the possibility of false-positive results using immunofluorescence or other antigen detection methods, specimens should also be obtained for confirmation by viral isolation. Direct immunofluorescence staining for virus-infected cells is unreliable unless the specimen is obtained from a skin lesion and adequate numbers of cells are collected. Cells from oropharyngeal swabs or from CSF should not be tested using this method.

Clinical specimens should be transported to the diagnostic virology laboratory without being frozen, and their processing should be expedited to permit rapid confirmation of the clinical diagnosis. In addition to skin vesicles, other materials or sites from which virus may be isolated include the CSF, stool, urine, throat, nasopharynx, and conjunctivae. Isolation of virus from swabs of superficial sites, such as the nasopharynx, may represent transient presence of the virus in secretions, when the culture is obtained within the first 24 hours after birth, and particularly when the specimen is taken immediately after birth.

Typing of an HSV isolate may be done by one of several techniques. Because the outcome of antiviral treatment and risk of late sequelae may be related to the virus type, typing is of prognostic and epidemiologic importance [94]. Results of viral cultures of the CSF may be positive for infants with disseminated HSV infections, but are usually negative for infants who have localized encephalitis.

Detection of HSV DNA in CSF by PCR can allow a rapid presumptive diagnosis of HSV encephalitis in the newborn [119–122]. PCR was used in the retrospective analysis of materials collected from 24 infants enrolled in the NIAID CASG antiviral studies [120]. HSV was detected by PCR assay of CSF in 71% of infants before antiviral therapy was initiated. At least one specimen was positive in 76% of infants, and all samples that were positive by viral culture were positive by PCR. Similar findings were reported by Swedish investigators when stored CSF specimens obtained from infants with neonatal HSV infection were tested for HSV by PCR. HSV DNA was detected from CSF in the acute phase of illness from 78% of patients with CNS disease [123].

Use of HSV PCR methods on CSF can potentially decrease the duration of time to diagnosis of some cases of HSV encephalitis; however, there are reports in older patients of initial negative HSV PCR results early in the course of illness. CSF obtained 4 to 7 days after the initial CSF samples was subsequently positive for HSV DNA in a few patients [124].

PCR tests of CSF were positive in 7 (24%) of 29 infants enrolled in the NIAID CASG antiviral studies whose clinical disease seemed to be limited to mucocutaneous lesions. Five of the six infants who were evaluated when 1 year old were developmentally normal [120]. The significance of this observation for disease classification and prognosis remains to be determined.

Most studies of PCR for the diagnosis of HSV CNS infections indicate the test is sensitive in approximately 75% to 100% of cases in small cohorts of infants [120–123]. Specificity of the test ranges from 71% to 100%. The broad range of values for sensitivity and specificity of HSV PCR probably results from different study methods and disease classifications [125].

Some studies have shown that HSV PCR may be used to detect HSV DNA in peripheral blood mononuclear cells and plasma of infants with proven neonatal HSV infection. Using a sensitive and well-standardized PCR method, investigators found HSV DNA in peripheral blood mononuclear cells of 6 of 10 infants tested and in plasma of 4 of 6 infants tested [91]. Other investigators have reported the presence of HSV DNA in serum of 67% (20 of 30) of infants with neonatal HSV infection [123].

In clinical practice, there is considerable interlaboratory variability in HSV PCR test performance. Diagnostic laboratories that perform HSV PCR testing must be able to validate their test and participate in national and in-house proficiency testing programs [126]. Interpretation of negative or positive HSV PCR results must depend on clinical findings. A negative PCR result for HSV in CSF in the setting of clinical, laboratory, or radiologic findings consistent with CNS infection does not rule out HSV infection. It is important to continue to use standard clinical and laboratory diagnostic methods for the evaluation of infants with possible neonatal HSV (Table 26–3).

Every effort should be made to confirm HSV infection by viral isolation. Cytologic examination of cells from the infant's lesions should not be used to diagnose HSV infection because reliable specific methods are available. Cytologic methods, such as Papanicolaou, Giemsa, or Tzanck staining, have a sensitivity of only approximately 60% to 70%. A negative result must not be interpreted as excluding the diagnosis of HSV and a positive result should not be the sole diagnostic determinant of HSV infection in the newborn. Intranuclear inclusions and multinucleated giant cells may be consistent with, but not diagnostic of, HSV infection.

In contrast to some other neonatal infections, serologic diagnosis of HSV infection has little clinical value. The interpretation of serologic assays is complicated by the fact that transplacentally acquired maternal IgG cannot be differentiated from endogenously produced antibodies, making it difficult to assess the neonate's antibody status during acute infection. Serial type-specific antibody testing may be useful for retrospective diagnosis if a mother without a prior history of HSV infection has a primary infection late in gestation and transfers little or no antibody to the fetus. Therapeutic decisions cannot await a diagnostic approach based on comparing acute phase and

convalescent phase antibody titers. IgM production is delayed or does not occur in infected infants because of inherent immaturity in the immune response to systemic viral infections in the newborn, and commercially available assays for IgM antibodies to HSV have limited reliability. The results of specific laboratory tests for HSV should be used in conjunction with clinical findings and general laboratory tests, such as platelet counts, CSF analysis, and liver function tests, to establish a disease classification.

# TREATMENT

## BACKGROUND

The cumulative experience of the past 25 years shows that perinatally acquired HSV infections are amenable to treatment with antiviral agents. Acyclovir is the drug of choice [96]. Because most infants acquire infection at the time of delivery or shortly thereafter, antiviral therapy has the potential to decrease mortality and improve long-term outcome. The benefits that antiviral therapy can provide are influenced substantially by early diagnosis. The likelihood of disease progression in infants who acquire HSV infections is an established fact. Without treatment, approximately 70% of infants presenting with disease localized to the skin, eye, or mouth develop involvement of the CNS or disseminated infection. Treatment initiated after disease progression is not optimal because many of these children die or are left with significant neurologic impairment. Regardless of the apparently minor clinical findings in some cases, the possibility of HSV infection in the newborn requires aggressive diagnostic evaluation, and likely or proven infection mandates the immediate initiation of intravenous acyclovir therapy.

## ANTIVIRAL DRUGS

Historically, four nucleoside analogues have been used to treat neonatal herpes: idoxuridine, cytosine arabinoside, vidarabine, and acyclovir. Of these, the first three are nonspecific inhibitors of cellular and viral replication. The fourth, acyclovir, is monophosphorylated by HSV-specific thymidine kinases and then converted to its diphosphate and triphosphate forms by cellular enzymes. Acyclovir acts as a competitive inhibitor of HSV DNA polymerase and terminates DNA chain elongation [127]. Idoxuridine and cytosine arabinoside have no value as systemic therapy for any viral infection because of toxicity and equivocal efficacy. Vidarabine was the first drug shown to be efficacious; it decreased mortality and improved morbidity in cases of neonatal HSV infections [128]. A comparison of vidarabine with acyclovir suggests that these compounds have a similar level of activity for this disease; however, vidarabine is no longer available for clinical use [115]. Acyclovir is safe for use in newborns and is familiar to pediatricians from its other clinical uses.

Acyclovir has been established as efficacious for the treatment of primary genital HSV infection [129,130]. Oral and intravenous administration of acyclovir to the immunocompromised host decreases the frequency of reactivation after immunosuppression and the duration of disease [131]. Acyclovir has been established to be superior to vidarabine for the treatment of HSV encephalitis in older children and adults [132]. Because this compound is a selective inhibitor of viral replication, it has a low frequency of side effects. After pharmacokinetic and tolerance evaluation of acyclovir were done in infants [133,134], the NIAID CASG compared vidarabine and acyclovir for the treatment of neonatal HSV infection in a randomized trial [115]. The dose of vidarabine used was 30 mg/kg/day, and acyclovir was given at a dose of 10 mg/kg every 8 hours. The duration of therapy was 10 days. There were no significant differences in survival between the two treatment groups (Fig. 26–3). There were no differences in adverse effects or laboratory evidence of toxicity.

Survival with antiviral therapy depended on classification of the extent of disease at diagnosis (Fig. 26–4). Mortality and morbidity were also influenced by clinical status at the time of diagnosis and the virus type. Among infants with skin, eye, or mouth disease, those with HSV-1 infections were all normal developmentally at 1 year compared with 86% of infants with HSV-2 infections. Infants who were alert or lethargic when treatment was initiated had a survival rate of 91% compared with 54% for infants who were semicomatose or comatose; similar differences in survival rates related to neurologic status were observed in infants with disseminated infection. Prematurity, pneumonitis, and disseminated intravascular coagulopathy were poor prognostic signs [94].

Improved outcome compared with historical data probably reflects earlier diagnosis and institution of antiviral therapy, preventing progression of disease from skin, eye,

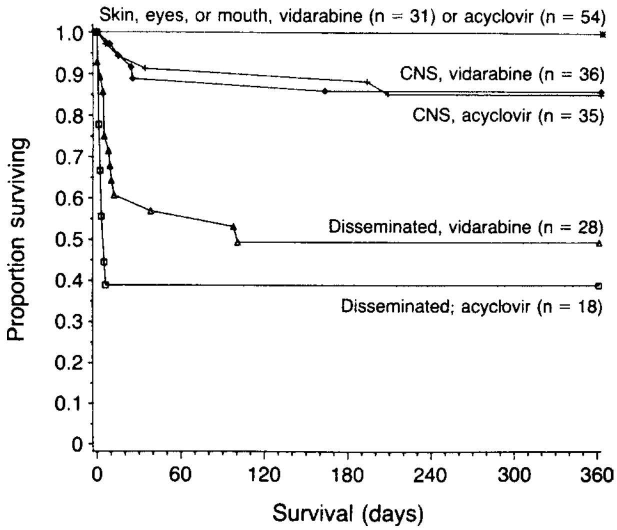

**FIGURE 26–3 Survival of infants with neonatal herpes simplex virus infection according to treatment and extent of disease.** The infection was classified as confined to skin, eyes, or mouth; affecting the central nervous system (CNS); or producing disseminated disease. After adjustment for extent of disease with use of a stratified analysis, overall comparison of vidarabine with acyclovir was not statistically significant ($P = .27$) by a log-rank test. No comparison of treatments within disease categories was statistically significant. *(From Whitley R, et al. A controlled trial comparing vidarabine with acyclovir in neonatal herpes simplex virus infection. N Engl J Med 324:444, 1991.)*

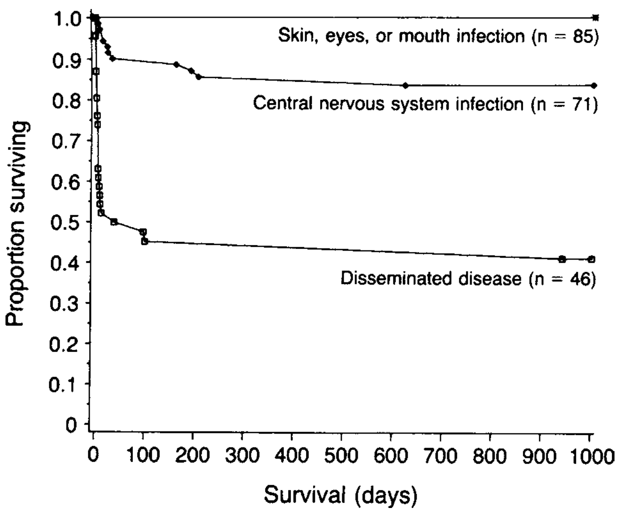

**FIGURE 26–4** Survival of infants with neonatal herpes simplex virus infection according to extent of disease ($P < .001$ for all comparisons). *(From Whitley R, et al. Predictors of morbidity and mortality in neonates with herpes simplex infections. N Engl J Med 324:450, 1991.)*

or mouth to more severe disease. The mean duration of symptoms before treatment for all participants, regardless of disease classification, was 4 to 5 days, indicating that therapy might have been instituted even sooner. These observations suggested that further advances in therapeutic outcome might be achieved by earlier intervention. Despite advances in laboratory diagnosis and treatment of neonatal HSV, the mean time between onset of disease symptoms and initiation of antiviral therapy has not changed [74].

Despite the proven efficacy of antiviral therapy for neonatal HSV infection, the mortality rate remains high, and many infants who survive disseminated or CNS disease have serious sequelae. This circumstance dictated the need to evaluate high doses of acyclovir and longer treatment regimens. Infants were enrolled in an NIAID CASG assessment of acyclovir given at an intermediate dose (45 mg/kg/day) or high dose (60 mg/kg/day). Mortality rates for infants with disseminated or CNS disease were lower for infants given high-dose acyclovir than observed in earlier studies (Fig. 26–5) [135]. There was no significant difference in morbidity status at 12 months of follow-up between high-dose and standard-dose acyclovir recipients for each of the three disease categories. Transient and reversible neutropenia occurred more frequently during high-dose therapy, but resolved during or after cessation of treatment. The dose of acyclovir used had no impact on the duration of viral shedding [135].

The current recommendation for treatment of neonatal HSV infection is acyclovir, 60 mg/kg/day in three doses (20 mg/kg/dose) given intravenously. Disseminated and CNS infections are treated at least 21 days. Duration of treatment for skin, eye, and mouth infection, after disseminated and CNS infection have been ruled out, is a minimum of 14 days [136]. The use of oral acyclovir is contraindicated for the treatment of acute HSV infections in newborns. Its limited oral bioavailability results in plasma and CSF concentrations of drug that are inadequate for therapeutic effects on viral replication. Other oral antiviral drugs, such as valacyclovir, have not been studied in infants and should not be used to treat acute HSV infection in newborns. The high risk of progression from localized mucocutaneous infections requires the administration of intravenous acyclovir to these infants, regardless of how well they seem at the time of diagnosis. In addition to intravenous therapy, infants with ocular involvement caused by HSV should receive one of the topical ophthalmic agents approved for this indication. Topical acyclovir is unnecessary for treatment of mucocutaneous lesions caused by HSV because parenteral drug reaches these sites.

Acyclovir treatment is based on clinical suspicion and laboratory diagnosis of neonatal HSV infection. Rapid methods, including direct antigen detection and PCR, should be used to facilitate early laboratory confirmation of suspected cases. Presumptive treatment is a reasonable option when circumstances prevent rapid laboratory diagnosis, and the clinical manifestations are those described for mucocutaneous infections, disseminated disease, or HSV encephalitis. These clinical manifestations could include skin lesions, seizures, hepatitis, hypothermia or fever, an ill-appearing infant, and CSF pleocytosis. Determining which infants admitted to the hospital with presumed sepsis should be treated empirically with acyclovir remains a topic of debate [137,138]. In all cases of presumptive therapy, specimens should be obtained for laboratory testing to guide the decision to continue treatment. During the course of therapy, careful monitoring is important to assess the therapeutic response. Even in the absence of clinical evidence of encephalitis, evaluation of the CNS should be done for prognostic purposes. Serial evaluations of hepatic and hematologic parameters may indicate changes caused by the viral infection or by drug toxicity.

Intravenous acyclovir is tolerated well by infants. Adequate hydration is necessary to minimize the risk of

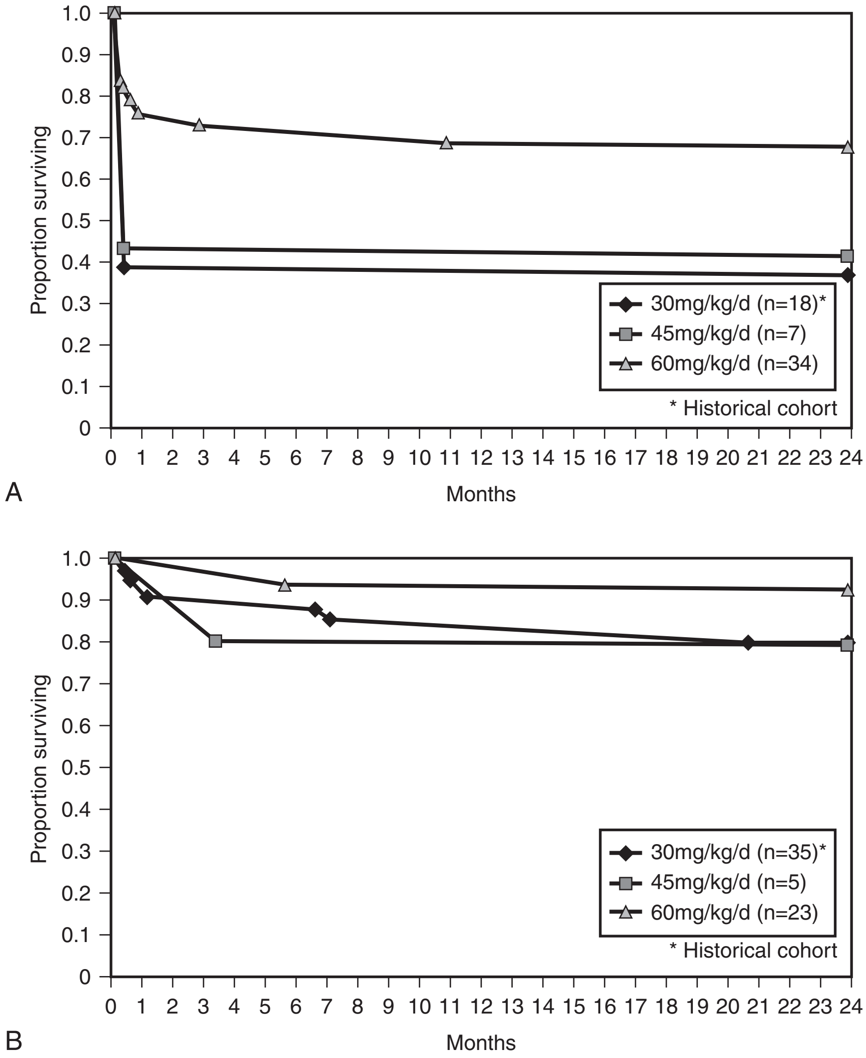

**FIGURE 26–5** **A** and **B,** Mortality rates for patients with disseminated disease (**A**) and central nervous system disease (**B**) depending on dose of acyclovir. *(Data from Kimberlin DW, et al. Safety and efficacy of high-dose intravenous acyclovir in the management of neonatal herpes simplex virus infections. Pediatrics 108:230-238, 2001.)*

nephrotoxicity, and dosage adjustments are necessary if renal clearance is impaired. As for all drugs, the possibility of acute toxicity should be considered in any child receiving parenteral antiviral therapy and should be assessed by serially evaluating bone marrow, renal, and hepatic functions. The potential for long-term harm from these drugs remains to be defined; so far, no long-term adverse effects have been identified.

Acyclovir resistance has been reported in an infant with acute HSV infection of the larynx in the newborn period; in this case, the initial isolate was not inhibited by acyclovir, although the source of this infection could not be explained [139]. Acyclovir resistance has also been reported in a premature infant with cutaneous and CNS disease caused by an initially acyclovir-susceptible HSV. The infant developed recurrent disseminated HSV infection 8 days after a 21-day course of acyclovir. The virus isolated at the onset of recurrent symptoms was found to lack thymidine kinase activity on the basis of a frameshift mutation in the thymidine kinase gene [140]. Another infant born to a mother with severe systemic primary HSV-2 infection developed an acyclovir-resistant mutant during acyclovir therapy for disseminated HSV infection and eventually died. The use of steroids to treat blood pressure instability may have hampered this infant's immune response to infection further [141].

Isolates of HSV recovered from infants who received intravenous acyclovir for cutaneous disease in the newborn period and had subsequent recurrent cutaneous lesions typically remain sensitive to acyclovir [142]. Emergence of viral resistance to acyclovir has been described in patients requiring prolonged or repeated treatment with this drug. One infant who was given long-term oral acyclovir for suppression of recurrences during the first 6 months of life had a resistant HSV isolated from a lesion after therapy was discontinued, but subsequent isolates were susceptible [143].

Antiviral resistance does not generally explain the failure of infants with the disseminated or encephalitic form of the disease to respond well to antiviral therapy. Clinical deterioration, despite appropriate therapy and supportive care, can be attributed to virus-induced destruction of cells compromising infected organs, such as liver or brain, or irreversible changes, such as disseminated intravascular coagulopathy.

The observation of an association between late sequelae and frequent recurrences of skin lesions in infants who

were treated for localized HSV-2 infections during the newborn period has raised questions about the potential efficacy of suppressive therapy with oral acyclovir. The NIAID CASG has undertaken an assessment of the safety and efficacy of suppression as an adjunct after the recommended treatment of mucocutaneous disease with intravenous acyclovir [143]. Infants were given 300 mg/m$^2$ two or three times per day for 6 months. Of 16 infants given the three daily doses, 13 (81%) had no recurrences of lesions while receiving therapy compared with 54% of infants from earlier studies who received intravenous acyclovir only. Of the 26 infants, 46% developed neutropenia. In one infant, suppressive therapy was associated with a transient recurrence of infection owing to an acyclovir-resistant isolate of HSV-2; subsequent recurrences were caused by susceptible isolates. Whether this effect on cutaneous recurrences, which was limited to periods of active oral suppressive therapy, has any effect on late neurologic sequelae is unknown.

A pilot study showed improved neurodevelopmental outcomes (compared with historical data) in a small group of infants treated with oral acyclovir for 2 years [144]. There was no comparative treatment group. Acyclovir therapy was relatively well tolerated in this small cohort of children; rare neutropenia and dental decay were reported. The dental decay was attributed to sugar in the acyclovir suspension.

Cases of breakthrough CNS HSV disease may occur despite oral acyclovir prophylaxis [145]. Until more published information becomes available regarding optimal dosing, duration, efficacy, and safety, oral acyclovir prophylaxis after neonatal HSV infection is not routinely recommended. Any decision to consider its use should be made in consultation with a pediatric infectious disease specialist or as part of a research protocol.

## OTHER ISSUES IN ACUTE MANAGEMENT

Neonates with HSV infection should be hospitalized and managed with contact precautions if mucocutaneous lesions are present. Many infants with this infection have life-threatening problems, including disseminated intravascular coagulation, shock, and respiratory failure, and they require supportive care that is available only at tertiary medical centers.

There is no indication that administration of immunoglobulin or hyperimmunoglobulin is of value for the treatment of neonatal HSV infection. Although a series of studies have suggested that the quantity of transplacental neutralizing antibodies affects the attack rate among exposed infants and may influence the initial disease manifestations, the presence of antibodies may or may not influence the subsequent course of infection [49,50,53,54,86]. The administration of standard preparations of intravenous immunoglobulin does not enhance the titers of functional antibodies against HSV in infants with low birth weight [146]. The evaluation of virus-specific monoclonal antibodies in combination with antiviral therapy may become feasible as new technologies for deriving human or humanized antibody preparations are developed [147].

No other forms of adjunctive therapy are useful for treating neonatal HSV infections. Various experimental modalities, including interferon, immunomodulators, and immunization, have been attempted, but none has produced demonstrable effects.

## LONG-TERM MANAGEMENT OF INFECTED INFANTS

With the advent of antiviral therapy, an increasing number of newborns with HSV infection are surviving and require careful long-term follow-up. The most common complications of neonatal HSV infection include neurologic and ocular sequelae that may be detected only on long-term follow-up. It is necessary that these children receive serial long-term evaluation from qualified pediatric specialists in these areas, which should include neurodevelopmental, ophthalmologic, and hearing assessments.

Recurrent skin vesicles are present in many children, including children who did not have obvious mucocutaneous disease during the acute phase of the clinical illness. Skin vesicles provide a potential source for transmission of infection to other children or adults who have direct contact with these infants. The use of day care for children, including children surviving neonatal HSV infections, stimulates many questions from day care providers about these children. There is some risk that children with recurrent HSV skin lesions would transmit the virus to other children in this environment. The most reasonable recommendation in this situation is to cover the lesions to prevent direct contact. HSV-1 is much more likely to be present in the day care environment in the form of asymptomatic infection or gingivostomatitis. In both cases, virus is present in the mouth and pharynx, and the frequent exchange of saliva and other respiratory droplets that occurs among children in this setting makes this route of transmission more likely. Education of day care workers and the general public about herpesvirus infections, their implications, and the frequency with which they occur in the population as a whole can calm fears and correct common misconceptions.

Parents of children with neonatal HSV infection often have significant guilt feelings. Parents often require support from psychologists, psychiatrists, or counselors. The family physician or pediatrician can provide a valuable supportive role to the family in this situation. Most parents and many physicians are unaware of the high prevalence of HSV-2 infection in the United States and of the lifelong persistence and subclinical nature of these infections. Concern about the risk of fetal and neonatal infection during subsequent pregnancies is often a major issue that can be addressed effectively based on the low risks as proven from large, prospective studies.

# PREVENTION

## BACKGROUND

Despite the progress that has been made in antiviral treatment of neonatal HSV infection, the ideal approach is to prevent the exposure of infants to active maternal infection at the time of delivery. Genital infections caused by HSV are often clinically silent when they are acquired as new infections and when the virus reactivates. With the

high prevalence of HSV-2 infection in the U.S. population, women are at risk for acquiring new genital infections during pregnancy, and at least one in five becomes infected before pregnancy. The problem of asymptomatic genital HSV infection means that the transmission of HSV from mothers to infants cannot be eliminated even with the best obstetric management.

It is futile to obtain sequential genital cultures during the last weeks of gestation in women with a history of genital herpes in an effort to identify those who will have asymptomatic infection at the onset of labor [48]. These cultures do not predict the infant's risk of exposure at delivery because of the usually brief duration of asymptomatic shedding and the time required for the culture to become positive. Because of the attention of the lay press to the devastating outcome of neonatal HSV infections, many women who know that they have genital herpes experience severe anxiety about the potential risks to the fetus and the newborn. As a consequence these women may have an unnecessarily high frequency of cesarean deliveries. The risk of neonatal HSV infection in the newborn is approximately equivalent for women who have no prior history of genital herpes or a partner with known infection (Table 26–4).

## MANAGEMENT OF PREGNANT WOMEN WITH KNOWN GENITAL HERPES

Women who have a history of recurrent genital herpes should be reassured that the risk of fetal or neonatal infection is very low. Intrauterine HSV infections are rare, with an estimated overall risk of 1 in 200,000 pregnancies [68]. Information about the risk of exposure to asymptomatic reactivation at delivery derived from six large-scale prospective studies is sufficient to conclude that the incidence of asymptomatic reactivation in these women is about 2% and that the attack rate for their exposed infants is approximately 3% or less; the risk of neonatal infection under these circumstances is less than 1 in 2000 deliveries.

Because laboratory methods cannot be used to detect asymptomatic infection in a timely manner, the current approach to management is to perform a careful vaginal examination at presentation and to elect cesarean delivery if the mother has signs or symptoms of recurrent genital herpes at the onset of labor. Given the low probability of neonatal infection, it is appropriate to deliver infants of women who have a history of recurrent genital herpes but who have no active clinical disease at delivery by the vaginal route [55]. An analysis of the occurrence of HSV infections in infants in California showed no change from 1985–1995, despite a documented decrease in deliveries by cesarean section and an increase in the proportion of women with a previous diagnosis of genital herpes whose infants were delivered vaginally [61].

A culture for HSV obtained at the time of delivery may be useful in establishing whether the virus was present at delivery to facilitate recognition of neonatal infection if it occurs. The value of this approach has not been established, however. Alternative diagnostic approaches, such as those based on PCR to detect virus, may ultimately expedite identification of women at risk for delivering infected infants [148,149]. Evidence indicates that detection of viral presence in genital samples by PCR is more sensitive than culture methods. The significance of a positive PCR result in predicting risk of transmission of HSV to the infant is unknown, however [150]. Viral DNA can persist for a longer interval than infectious virus.

The utility of suppressive therapy of genital herpes in women with a known history of recurrent infection remains a question for clinical investigation because of risk-benefit considerations. Some studies indicate that prophylactic acyclovir reduces the number of genital lesions from HSV. Despite prophylaxis, a few women continue to have virus detectable by PCR [150]. Use of prophylactic valacyclovir also reduced clinical HSV recurrences, but did not decrease shedding of HSV within 7 days of delivery compared with placebo [151]. Even with suppressive therapy, the potential for neonatal HSV infection is not eliminated entirely. It is unknown whether acyclovir suppressive therapy late in pregnancy might alter the clinical presentation of neonatal HSV or compromise the interpretation of viral cultures [152].

The pharmacokinetics and metabolism of acyclovir in the human fetus are unknown. The possibility of fetal nephrotoxicity related to acyclovir is a potential risk that must be considered. Whether acyclovir treatment of mothers with primary genital herpes late in gestation can reduce the neonatal risk of these infections is a research issue. Signs of disseminated herpes in the mother warrant the administration of intravenous acyclovir, however.

Based on limited scientific evidence, the American College of Obstetricians and Gynecologists recommends that women with active recurrent genital herpes should be offered suppressive viral therapy at or beyond 36 weeks of gestation until delivery [55]. Universal antenatal type-specific HSV screening to prevent neonatal HSV is not recommended [153].

**TABLE 26–4** Projected Risk of Transmission of Herpes Simplex Virus Type 2 (HSV-2) from Mothers to Infants at Delivery in a Cohort of 100,000 Pregnant Women

| 25% with Past HSV-2 Infection | 75% Susceptible to HSV-2 Infection |
|---|---|
| 25,000 women | 75,000 women |
| 1.5% reactivation at delivery | 0.02% seroconversion/wk |
| 375 women with reactivation | 30 women with infection <2 wk before delivery |
| <5% risk of transmission to infant | 50% risk of transmission |
| 19 infected infants | 15 infected infants |

## MANAGEMENT OF INFANTS OF MOTHERS WITH GENITAL HERPES

Infants of mothers with histories of genital herpes delivered vaginally or by cesarean section and whose mothers have no evidence of active genital herpetic infection are at low risk for acquiring neonatal HSV infection. These infants need no special evaluation during the newborn

period. Infants delivered vaginally to mothers with an active genital HSV infection or who have genital cultures done at delivery that are positive for HSV should be isolated from other infants for the durations of their hospitalization up to age 4 weeks. Parents and primary care physicians should be notified about the exposure of the infant so that the infant can be observed for the occurrence of nonspecific signs consistent with possible neonatal herpes. The parents and responsible family members should be educated about the low risk of transmission to relieve anxiety and to ensure prompt return for care in the unlikely event that signs of infection appear. Information regarding infection should include a description of the risks associated with transmission of infection to the newborn, the common signs and symptoms of neonatal herpes, the necessity for careful monitoring for the onset of illness 4 to 6 weeks after birth, and the planned approach to treatment if symptoms occur.

It may be useful to obtain cultures from the exposed infant 24 to 48 hours after delivery and at intervals during the first 4 weeks of life. Sites from which virus may be recovered include the eye, oropharynx, and skin lesions that are suspected to be herpetic. Weekly viral cultures have been suggested for the surveillance of exposed infants; the utility of this approach has not been proved by prospective studies, and it should be considered an optional addition to clinical observation.

If cultures from any site in the infant are positive, a thorough diagnostic evaluation should be done, including obtaining additional specimens for viral culture from the site that was reported to be positive, the oropharynx, and the CSF, and treatment with intravenous acyclovir should be initiated. Viral cultures of urine and HSV PCR of peripheral blood mononuclear cells may also be considered to identify additional sites of viral infection. A positive HSV PCR result in addition to the initial positive culture can provide additional evidence to support the diagnosis of HSV infection. A negative HSV PCR result does not in itself rule out infection.

No data are available to support the administration of acyclovir to exposed infants who have no clinical signs or laboratory evidence of infection. Parameters for duration of such prophylaxis cannot be defined. The experience from other clinical settings is that the virus is suppressed only for the period the drug is given and is not eradicated. Careful clinical follow-up of these infants, with immediate institution of antiviral therapy if symptoms occur, is an appropriate approach.

An issue of frequent concern is whether the mother with an active genital HSV infection at delivery should be isolated from her infant after delivery. Women with recurrent orolabial HSV infection and cutaneous HSV infections at other sites (e.g., breast lesions) are at similar risk for transmission of virus to their newborns. Because transmission occurs by direct contact with the virus, appropriate precautions by the mother, including careful hand washing before touching the infant, should prevent any need to separate mother and child. In some cases, it is possible to have the exposed infant room-in with the mother as a means of isolating the infant from other newborns. Breast-feeding is contraindicated if the mother has vesicular lesions involving the breast.

## CONCLUSION

Neonatal HSV infection is a life-threatening disease in the newborn. With an increasing prevalence of genital herpes and the recognition that many infections are completely asymptomatic in the mother, pediatricians, neonatologists, obstetricians, and family practitioners must continue to remain vigilant to infants whose symptoms may be compatible with HSV infections. Early identification leads to prompt treatment. It is hoped that the development of safe and efficacious vaccines and a better understanding of factors associated with transmission of virus from mother to infant will enable prevention of neonatal HSV infection.

## ACKNOWLEDGMENTS

The databases on clinical presentations, diagnosis, and antiviral treatment of neonatal HSV infections have been generated through the efforts of the NIAID Collaborative Antiviral Study Group for more than 25 years, with support from the National Institute of Allergy and Infectious Diseases. The institute has also supported prognostic studies of HSV infection in pregnancy and newborns in the United States.

CHAPTER 27

# Human Parvovirus

**Stuart P. Adler** ❂ **William C. Koch**

CHAPTER OUTLINE

The parvoviruses are a family of single-stranded DNA viruses that have a wide cellular tropism and broad host range, causing infection in invertebrate species and vertebrates, from insects to mammals. Although many parvoviruses are important veterinary pathogens, there are only two human pathogens in the family: human parvovirus B19 and the more recently described human bocavirus [1,2]. Human bocavirus seems to be primarily a respiratory pathogen of young children and is not discussed further here. Human parvovirus B19 is most commonly referred to as parvovirus B19 or simply B19. A new genus and name have been proposed for this virus, *Erythrovirus* B19 [3], based on its cellular tropism for erythroid lineage cells and to distinguish it from the other mammalian parvoviruses. Compared with most other common human viruses, B19 is a relatively new pathogen, but since its initial description B19 has come to be associated with a variety of seemingly diverse clinical syndromes in many different patient populations (Table 27–1). Although the list of clinical manifestations caused by B19 infection is probably not yet complete, some proposed relationships, such as to rheumatologic disease and neurologic disorders, remain controversial [4,5],

Parvovirus B19 was accidentally discovered by Cossart and associates [6] in 1975 as an anomalous band of precipitation while screening blood donor serum for hepatitis B antigen by counterimmunoelectrophoresis. The name *B19* refers to the donor unit from which it was originally isolated. Initial analysis of the new virus revealed it had physical features characteristic of the known parvoviruses [7],

DOI: 10.1016/B978-1-4160-6400-8.00027-4

**TABLE 27–1** Clinical Manifestations Associated with Parvovirus B19 Infection

| Diseases | Primary Patient Groups |
|---|---|
| ***Diseases Associated with Acute Infection*** | |
| Erythema infectiosum (fifth disease) | Normal children |
| Polyarthropathy | Normal adolescents and adults |
| Transient aplastic crisis | Patients with hemolytic anemia or accelerated erythropoiesis or both |
| Papular-purpuric “gloves and socks” syndrome | Normal adolescents and adults |
| ***Diseases Associated with Chronic Infection*** | |
| Persistent anemia (red blood cell aplasia) | Immunodeficient or immunocompromised children and adults |
| Nonimmune fetal hydrops | Intrauterine infection |
| Congenital anemia | Intrauterine infection |
| Chronic arthropathy | Rare patients with parvovirus B19–induced joint disease |
| Infection-associated hemophagocytosis | Normal or immunocompromised patients |
| Vasculitis or purpura | Normal adults and children |
| Myocarditis | Intrauterine infection, normal infants and children, immunocompromised patients |

*Adapted from Young NS, Brown KE. Parvovirus B19. N Engl J Med 350:586–597, 2004.*

allowing classification in this family. Because the donors from whom it was originally isolated were asymptomatic, B19 infection was not initially associated with any illness, and for the next several years after its description it was a virus in search of a disease.

In 1981, Pattison and colleagues [8] noted a high prevalence of antibodies to this virus in the serum of children hospitalized with transient aplastic crisis of sickle cell disease and proposed B19 as the viral cause of this clinically well-described event. Serjeant and colleagues [9] later confirmed this association in population studies of sickle cell patients in Jamaica. In 1983, 8 years after its initial description, Anderson and coworkers [10] proposed B19 as the cause of the common childhood exanthem erythema infectiosum (EI), or fifth disease. The name *fifth disease* derives from the 19th century practice of numbering the common exanthems of childhood—EI was the fifth rash designated in this scheme, and it is the only one for which this numeric designation has persisted in clinical practice [11]. The others in the series included measles, scarlet fever, rubella, and Filatov-Dukes disease (a mild variant of scarlet fever that is no longer recognized).

The possibility of fetal disease associated with EI was considered long before the viral etiology was known primarily because of comparison with rubella and the incidence of congenital rubella syndrome after community epidemics [12–14]. Advances in knowledge of the virology of other animal parvoviruses and their known propensity to cause disease in the fetus and newborn animal further fueled this concern [15]. This suspicion was confirmed in 1984 when two reports of B19 infection in pregnant women associated with adverse fetal outcomes appeared [16,17] and were later followed by a larger report of a series of cases of nonimmune hydrops fetalis caused by intrauterine infections with B19 [18]. Over the ensuing decade, various clinical manifestations associated with acute and chronic infection have since been attributed to this virus in different patient groups (see Table 27–1).

Since the initial reports of fetal infection, knowledge of the epidemiology, pathophysiology, and short-term outcome of fetal and neonatal infection with B19 has increased immensely based on numerous large population-based studies [19–23]. B19 infection during pregnancy has probably been the subject of more such studies than any of the other manifestations with the possible exception of transient aplastic crisis of sickle cell disease. There is still much to be learned, however, regarding the long-term outcome of fetal infection, unusual clinical manifestations of infection in neonates, and the immunologic response to infection. Lastly, the potential for prevention through vaccine development is a topic of current interest and ongoing research.

## MICROBIOLOGY

Similar to other members of the family Parvoviridae, parvovirus B19 is a small, nonenveloped, single-stranded DNA virus. The taxonomy for this family has been revised to include two subfamilies, the Densovirinae, which are insect viruses, and the Parvovirinae, which infect vertebrates [24,25]. The Parvovirinae subfamily is composed of three genera: *Dependovirus*, *Parvovirus*, and *Erythrovirus*. Viruses of the *Dependovirus* genus require coinfection with another unrelated helper virus (adenovirus or herpesvirus) to complete their life cycle. Some *Dependovirus* strains infect humans (e.g., adeno-associated viruses), but the infection is asymptomatic and without consequence. In contrast to *Dependovirus* strains, members of the genera *Parvovirus* and *Erythrovirus* are able to replicate autonomously. Previously included in the genus *Parvovirus*, B19 is now classified as an *Erythrovirus*. At present, the genus *Erythrovirus* consists of only two members: B19 and a simian parvovirus that has a similar genomic organization as B19 and has a similar tropism for erythroid cells [26]. Although many parvoviruses are pathogenic to other mammals (e.g., canine parvovirus, feline panleukopenia virus), B19 and human bocavirus are the only parvoviruses proven to cause disease in humans.

There is only one recognized serotype of B19. Minor variations in the nucleotide sequence occur among different B19 viral isolates from different geographic areas, but these have not been definitely shown to affect clinical patterns of infection or pathogenicity [27–29]. Two isolates of human parvovirus whose nucleotide sequence differs significantly (>10%) from B19 have been described, V9 and V6 [30,31]. Both were isolated from patients with transient red blood cell aplasia indistinguishable clinically from typical B19-induced aplastic crisis. The clinical significance of these variants and whether they represent

different genotypes or merely geographic variants of B19 remain topics of debate [29,32].

The B19 genome is very small (approximately 5.6 kb) and contained within an icosahedral protein capsid. The capsid structure and lack of an envelope make the virus very resistant to heat and detergent inactivation, features that seem to be important in transmission. The genome seems to encode only three proteins. Two are capsid proteins, designated VP1 and VP2. VP2 is smaller but more abundant and makes up approximately 96% of the capsid protein. VP1 is larger and makes up about 4% of the capsid, but contains a unique region that extends out from the capsid surface and serves as the attachment site for the cellular receptor [4]. VP2 has the unique ability to self-assemble into capsids that are morphologically and antigenically similar to B19 viruses when expressed in cell culture systems in vitro [33,34]. When present with VP1, the capsids incorporate proteins, but VP1 alone does not self-assemble [33].

The third gene product is a nonstructural protein designated NS1. The function of this protein is unclear, but it has been shown to be involved in regulation of the viral promoter and seems to have a role in DNA replication [25]. Studies of NS1 have been hampered by the observation that it seems to be toxic to cells by an unknown mechanism [35]. More recent studies have further suggested that production of NS1 can lead to programmed cell death (apoptosis) mediated by stimulation of cytokine production [36,37].

Because of its limited genomic complement, B19 requires a mitotically active host cell for replication. It can replicate only in certain erythroid lineage cells stimulated by erythropoietin, such as erythroid precursors found in bone marrow, fetal liver, umbilical cord blood, and a few erythroleukemic cell lines [25,38–42]. B19 cannot be propagated in standard cell cultures [43], a fact that had previously limited the availability of viral products for development of diagnostic assays. Much of this limitation has been overcome by the development of molecular methods for the detection of viral nucleic acid, but reliable commercial serologic assays are still limited.

The cellular receptor for the virus has been identified as globoside, a neutral glycosphingolipid that is present on erythrocytes where it represents the P blood group antigen [44]. The presence of this lipid is necessary for viral infection to occur, and individuals who lack this antigen (p phenotype) are naturally immune to B19 infection [45]. The P antigen is also present on other cells, such as endothelial cells, fetal myocardial cells, placenta, and megakaryocytes [44]. The tissue distribution of this receptor may explain some of the clinical manifestations of infection with this virus (see “Clinical Manifestations Other than Intrauterine Infection”).

Although the P antigen is necessary for B19 viral infection, it is insufficient because some cells, particularly nonerythroid tissues, that express the receptor are incapable of viral infection [46]. More recently, a coreceptor has been described on human cells that are permissive for B19 infection [47]. The hypothesis is that the globoside is necessary for viral attachment, but the coreceptor somehow allows for viral entry into the cell where viral replication can occur. If confirmed, this hypothesis may provide an alternative explanation of the pathogenesis of infection in nonerythroid tissues that express globoside without the coreceptor.

## GENERAL ASPECTS OF PATHOGENESIS

Parvovirus B19 requires a mitotically active host cell to complete its full replicative life cycle. The primary target for B19 infection seems to be erythroid progenitor cells that are near the pronormoblast stage of development. The virus can be propagated only in human erythroid progenitor cells from bone marrow, umbilical cord blood, fetal liver, peripheral blood, and a few erythroid leukemic cell lines [48]. B19 lytically infects these cells with progressive loss of targeted cells as infection proceeds. In vitro hematopoietic assays show that B19 suppresses formation of erythroid colony-forming units, and this effect can be reversed by addition of serum containing anti-B19 IgG antibodies [49].

The virus has little to no effect on the myeloid cell line in vitro, but causes inhibition of megakaryocytopoiesis in vitro without viral replication or cell lysis [50]. Clinically, this is best illustrated in transient aplastic crisis of sickle cell disease. Patients have fever, weakness, and pallor on presentation, with a sudden and severe decrease in their reticulocyte count. This cessation of red blood cell production coupled with the shortened red blood cell survival because of chronic hemolysis produces a profound anemia. Examination of the bone marrow typically reveals hypoplasia of the erythroid cell line and a maturational arrest; giant pronormoblasts are often seen with intranuclear viral inclusions [49]. With development of specific antibodies, viral infection is controlled, and reticulocyte counts begin to increase.

Evaluation of infection in normal volunteers has shown similar hematologic changes, but because of the longer life of red blood cells, these changes are clinically insignificant [51]. Adult volunteers inoculated intranasally with B19 developed viremia after 5 to 6 days with a mild illness. Their reticulocyte counts decreased to undetectable levels, and this was accompanied by a modest decline in hemoglobin and hematocrit. Platelets and granulocyte counts also declined. Specific antibody production with IgM followed by IgG developed, and viremia was cleared rapidly. A second phase of illness developed at 17 to 18 days with rash and arthralgias but without fever, and hematologic indices had returned to normal.

The tissue distribution of the cellular receptor for the virus (P antigen) may explain the predominance of hematologic findings associated with B19 infection. Its presence on other tissues may help to explain other clinical manifestations, such as myocardial disease, congenital infection, and vasculitis syndromes. Although the cellular receptor is present and the virus can attach, in contrast to the erythroid cell, these cells are nonpermissive for viral replication; that is, the virus is unable to undergo a complete life cycle with the resultant lysis of the host cells, as described previously. Instead, interaction in these tissues leads to accumulation of the nonstructural protein NS1. This protein is essential for viral replication and has various proposed functions [25], but it seems to be toxic to

most mammalian cell lines when present in excess [35]. NS1 has been associated with apoptosis and programmed cell death [37,42]. NS1 has also been linked to production of tumor necrosis factor-α and interleukin-6, a potent proinflammatory cytokine [36,42,52]. Cellular injury may occur through cytokine pathways and provide another mechanism aside from lytic infection for some of the clinical manifestations.

Chronic infections in immunocompromised patients develop when patients are unable to mount an adequate neutralizing antibody response. These infections are characterized by viral persistence in serum or bone marrow and lack of detectable circulating antibody. Clinical manifestations include chronic anemia or red blood cell aplasia and may include granulocytopenia and thrombocytopenia. The mechanism for leukopenia and thrombocytopenia is unknown, although it has been shown that B19 causes disturbances in megakaryocytic replication when infected in vitro [50].

# EPIDEMIOLOGY AND TRANSMISSION

## OVERVIEW

Parvovirus B19 is a highly contagious and common infection worldwide. In the United States, 60% or more of white adults are seropositive (have IgG antibodies to B19 in their sera). This seropositivity indicates a previous infection usually acquired in childhood. Among African Americans, the rate of seropositivity is about 30% [21]. Transmission of B19 from person to person is probably by droplets from oral or nasal secretions. This mode of transmission is suggested by the rapid transmission among individuals in close physical contact, such as schoolmates or family members, and from a study of healthy volunteers experimentally infected with B19, in whom virus was found in blood and nasopharyngeal secretions for several days beginning 1 or 2 days before symptoms appeared [51]. In the volunteer study, no virus was detected in urine or stool.

Given the highly contagious nature of B19 infections, it is not surprising that most outbreaks occur in elementary schools and occasionally child care centers. Susceptible seronegative adult school personnel are at high risk for acquiring the infection from students [21,53]. Some outbreaks in schools may be seasonal, often late winter and spring, and epidemic, with many children and staff acquiring the infection and developing symptoms of EI. At other times, the infection is endemic, with transmission occurring slowly and with only a few manifesting symptoms.

## GLOBAL DISTRIBUTION

Parvovirus B19 infections occur worldwide. Serologic evidence of B19 infection has been found everywhere studied, including developed countries, undeveloped countries, urban and rural areas, and isolated island populations [54–59]. The diseases and associated signs and symptoms are the same worldwide. No clinically or epidemiologically important strain or antigenic differences have been detected, and serologic assays are independent of the source or location of patient serum. Disease resulting from B19 seems to be unrelated to specific viral genotypes, although analysis of the antigenic variation or nucleotide sequences of widely dispersed B19 isolates shows some heterogeneity of unknown significance [27,28,60–65].

## SEASONALITY AND PERIODICITY

Transmission of parvovirus B19 continues throughout the year; however, there are seasonal variations in transmission rates. Outbreaks of EI most often occur in winter and spring in temperate climates and less frequently in fall and summer [66–68]. In schools or day care centers, outbreaks of EI may persist for months, usually starting in late winter or early spring and ending with summer vacation. Figure 27–1 highlights multiyear outbreaks of B19 exposure among pregnant women and the associated seasonal variation in Pittsburgh, Pennsylvania. Yearly, most cases occurred in late spring and summer.

In the island nation of Jamaica, careful studies of people with sickle cell disease showed that epidemics of transient aplastic crises occurred about every 5 years with little disease inside this interval [69]. Epidemics of B19 infections at 5-year intervals were also observed in

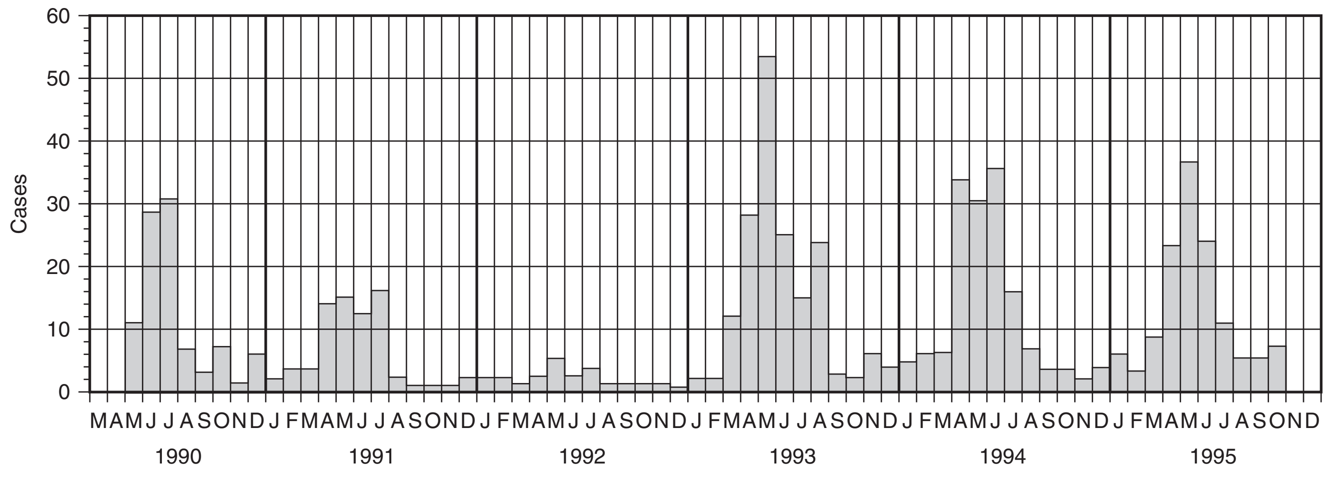

**FIGURE 27–1 Seasonal variation in reported parvovirus B19 exposures in pregnant women.** Each month is indicated by its first letter. *(Data from Harger J, Koch W, Harger GF. Prospective evaluation of 618 pregnant women exposed to parvovirus B19: risks and symptoms. Obstet Gynecol 91:413, 1998.)*

Rio de Janeiro, Brazil [70]. In Japan, age-related serologic evaluation of stored serum samples showed no evidence for B19 epidemics over a 10-year period [71]. The prevalence of IgG antibodies to B19 among three tribes of Amerindians living in remote regions of Brazil was very low (<11%), and in one tribe was zero for people younger than 30 years [57]. School nursing records in Iowa over 14 years identified cases of EI in all but one year [72].

## SEROPREVALENCE BY AGE

In numerous studies of parvovirus B19 infection based on serologic testing, the seroprevalence of B19 infection increases with age [6,69,73–78]. Figure 27–2 shows the age-dependent increase in seroprevalence from Richmond, Virginia [79]. Transplacentally acquired maternal antibodies are undetectable by 1 year of age. In children younger than 5 years, the prevalence of IgG antibodies to B19 is usually less than 5%. The greatest increase in seroprevalence and B19 infection occurs between 5 and 20 years of age. By age 20 years, the seroprevalence of B19 infection increases from about 5% at 5 years of age to nearly 40%. Afterward, without regard to risk factors, B19 seroprevalence increases slowly. In adult blood donors, the seroprevalence of IgG antibodies to B19 ranges from 29% to 79% (median 45%) [76–82]. By age 50, the seroprevalence may be greater than 75%. Similar results on age-related seroprevalence of B19 infections were observed in India [80–86].

## SEROPREVALENCE BY GENDER

In most studies, the prevalence of antibodies to parvovirus B19 in sera obtained from men and women is similar [59,74]. At least six studies have reported that women have a higher rate of B19 infection than men, however.* In one study of adult blood donors, the proportion of women who were seropositive, 47.5%, was 1.5 times higher than in men. The prevalence of IgG antibodies averaged 51% for women of all ages compared with 38% for men in one of two family studies in Richmond, Virginia, and 64% for women and 50% for men in the other [21,79]. In Taiwan, the prevalence of IgG antibodies to B19 among women was significantly higher than among men (36.4% versus 29.4%; $P < .001$) [89]. The most likely explanation for the higher rates of B19 infection among women compared with men is that women are likely to have more frequent contact with children, especially school-age children who, because of school attendance, are the major sources of B19 transmission. For adults, contact with school-age children is the major risk factor for B19 infection [21].

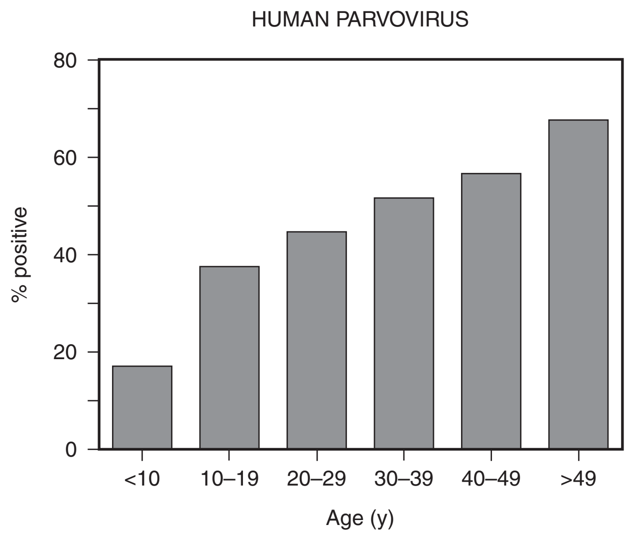

**FIGURE 27–2 Percentage of family subjects positive for IgG antibody to parvovirus B19 by age.** The sample includes 283 subjects from 111 families. Subjects were one twin of each twin pair, nontwin parents, and the oldest child of each family. *(Data from Adler SP, Koch W. Human parvovirus B19 infections in women of childbearing age and within families. J Pediatr Infect Dis 8:83, 1989.)*

## SEROPREVALENCE BY RACE

In the United States, there are significant differences in the seroprevalence to parvovirus B19 between African Americans and whites. In Richmond, Virginia, approximately 60% of whites are seropositive compared with 45% of African Americans [21]. The reasons for the lower rate of infection among African Americans are unknown, but likely reflect the racial segregation of children in schools.

## INCIDENCE

In tests of serum from random blood donors for evidence of a recent parvovirus B19 infection, the rate of infection using antigen detection is 0 to 2.6 per 10,000 individuals tested, with a median of 1 per 10,000, whereas using DNA detection, the rate is 0 to 14.5 per 10,000, with a median of 2 per 10 [90–95]. By contrast, when IgM antibodies to B19 were used to detect recent infection, the rate was zero, but all studies included less than 1000 patients [80,96,97]. As for seroprevalence, women may have a greater risk for infection during outbreaks of EI. During an epidemic of EI in Port Angeles, Washington, the attack rate for women was 15.6%, more than twice the rate of 7.4% for men [12].

In Spain and Chile, children have the highest rates of B19 infection, which is true for children ages 0 to 4 years and 5 to 9 years [98,99]. A study of 633 children with sickle cell disease followed at Children's Hospital in Philadelphia from 1996–2001 found that 70% were seronegative (susceptible), and during this period 110 of these patients developed B19 infections for an incidence of 11.3 per 100 patients per year [100]. Of the 110 patients infected, there were 68 episodes of transient aplastic crisis, characterized not only by an acute exacerbation of anemia, but also by acute chest syndrome, pain, and fever. The high incidence of disease among children with sickle cell disease emphasizes the need for a vaccine against B19.

## RISK FACTORS FOR ACQUISITION

Parvovirus B19 is efficiently transmitted among persons residing in the same home, with attack rates, based on the development of signs and symptoms of EI, of 17% to 30% [12,101]. Using serologic testing to identify asymptomatic infection and to exclude immune individuals, the secondary attack rate for susceptible household contacts is 50%. Most secondary cases of EI or aplastic crisis in

the home occur 6 to 12 days after symptoms develop in the index case [10,12,101–104]. A serologic study of pregnant Danish women indicated that seropositivity was significantly correlated with increasing number of siblings, having a sibling of the same age, number of own children, and occupational exposure of children [105].

During epidemics, B19 transmission is widespread among school-age children. Studies of school or classroom outbreaks of EI with at least one serologically confirmed case of acute B19 infection revealed student infection rates of 1% to 62% based on the occurrence of a rash illness. The median infection rate for all studies was 23% [106–113]. Because asymptomatic infections are common, and other signs and symptoms of EI may be mild and overlooked, these studies undoubtedly underestimate the true incidence of infection. Studies of students using serologic assays to identify B19 infection during outbreaks report infection rates of 34% to 72% with most not associated with a rash illness [107,112,113]. Higher rates of infection occur in elementary schools and day care centers compared with secondary schools, and in students in boarding schools compared with students who live at home [12,75,111–113].

During school epidemics, employees in contact with children have the highest rates of infection compared with community controls. The attack rate based on detection of rash illness or arthropathy may be relatively low—12% to 25% [107,111]. The seroprevalence of B19 IgG antibodies to B19 in school employees is greater than adult community controls, however—50% to 75% [21,113,114]. When serologic testing is used to identify employees with asymptomatic infection and to exclude immune employees, the attack rate among the susceptible individuals is usually very high. In four school outbreaks where serologic testing was used, the attack rate among teachers ranged from 19% to 84%, and the frequency of asymptomatic infection was greater than 50% in all but one outbreak [107,110,113,114]. The highest infection rates occurred among susceptible elementary school teachers compared with middle and high school teachers; this may reflect either exposure to more infected children or a greater likelihood of contact with respiratory secretions in younger children [113,114]. During a community-wide outbreak of EI in Connecticut in 1988, the infection rate among susceptible women was 16% for school teachers, 9% for day care workers and homemakers, but only 4% for other women working outside the home [113].

The risk of infection may be increased for school employees even in the absence of recognized epidemics of EI. In a study of 927 susceptible school employees conducted during a 3.5-year period when no community outbreaks were detected, the annual incidence of specific IgG seroconversion was 2.9% compared with 0.4% for a control population of 198 hospital employees [21]. The rate was higher, 3.4%, for school employees with jobs involving direct contact with children compared with only 0.6% observed for persons with jobs that did not involve contact with children [21]. Most (>50%) of the individuals who seroconverted did not recall an illness characterized by rash or arthropathy.

Salivary antibodies can be used to detect IgG and IgM antibodies to B19 because serum antibodies passively diffuse into saliva. Testing saliva for antibodies to B19 was useful in documenting outbreaks in schools and households. In an outbreak in England, school attack rates ranged from 8% to 50%, including an attack rate of 45% among the teaching staff [115]. The household transmission attack rate was 45% for 11 susceptible individuals. These rates are similar to what has been previously observed [115]. Crowding and low socioeconomic status are not proven risk factors for B19 infection. These risk factors are suggested, however, by the observation that in Rio de Janeiro, the seroprevalence of IgG antibodies to B19 is 35% in children age 5 years or younger, and in Niger it was 90% by 2 years of age [56,74].

## HOSPITAL TRANSMISSION

Parvovirus B19 can be transmitted from infected patients to hospital workers [111]. Most, but not all, investigations reveal that hospital transmission of B19 to laboratory personnel is common and includes direct patient-to-patient transmission and indirect transmission from materials or specimens known to contain B19 [116–119]. One patient with sickle cell anemia became ill with aplastic crisis 9 to 11 days after contact in the hospital with a patient with hereditary spherocytosis hospitalized for aplastic crisis; B19 infection was confirmed in both patients [120]. An outbreak of EI occurred on a pediatric ward where 13 (26%) of 50 children developed a rash illness [121]. B19 seroconversion occurred in 5 (71%) of 7 children with rash illness and in 9 (35%) of 26 children who were asymptomatic.

Transmission from patient to health care worker occurred twice in one hospital after admission of patients with aplastic crisis [116]. In the first case, 4 (36%) of 11 susceptible employees with close contact had IgM antibodies to B19, indicating recent infection; in the second case, 10 (48%) of 21 employees either had specific IgM antibodies to B19 or seroconverted from IgG negative to positive. Eleven (79%) of 14 employees were symptomatic with rash or arthropathy. Another study of an outbreak of EI among health care workers on a pediatric ward found that 10 (33%) of 30 susceptible health care workers had serologic evidence of acute B19 infection, along with 2 (17%) of 12 immunocompromised patients being cared for on the ward [117,122]. The two infected patients were not symptomatic, but analysis of preexisting sera showed they acquired B19 while hospitalized. Onset of symptoms among the employees was temporally clustered, indicating a chronic source, such as an immunocompromised patient or person-to-person transmission.

Studies in Hong Kong identified three immunocompromised patients who seemed to transmit genetically identical strains of B19 from patient to patient [123]. At least one of these three patients seemed to be able to transmit the virus over many months. Immunocompromised patients often have chronic infections and may be infectious for long periods. DNA sequence analysis was also used in Japan to document B19 transmission between hospital staff members, including nursing staff, office workers and a physiotherapist [124].

Other investigations have observed little, if any, risk for hospital transmission. No evidence of patient-to-employee transmission was found among 10 susceptible

health care workers with frequent contact with a chronically infected patient hospitalized for 24 days before institution of isolation precautions [125]. Transmission to hospital employees did not occur after exposure to a B19-infected mother, her infected stillborn fetus, and contaminated objects in the hospital room [126]. During a community outbreak of B19, none of 17 susceptible pregnant health care workers with possible exposure had serologic evidence (IgM antibodies to B19) of a recent infection [127]. In a case-control study of hospital transmission, serologic testing was used to determine the infection rates among personnel exposed to patients with sickle cell disease and transient aplastic crisis before the patients were placed in isolation [128]. Only 1 of 32 susceptible exposed hospital workers acquired a B19 infection compared with 3 of 37 susceptible workers not exposed. This study suggested that hospital workers who cared for patients with aplastic crisis were not at an increased risk for B19 acquisition.

Two prospective studies from one institution determined the incidence of infection in health care workers during endemic (nonepidemic) periods. The first study found the annual seroconversion rate to be 1.4% for 124 susceptible female health care workers followed for an average of 1.7 years. In a subsequent study of 198 susceptible hospital employees, the annual rate was 0.4% compared with 2.9% for school employees [21]. Taken as a whole, the evidence indicates that one must assume that B19 may be highly contagious in the hospital, although perhaps not in every circumstance. Many potential variables may affect rates of transmission from patients to staff, including the type of patient, immunocompromised status or nonimmunocompromised status, the duration of B19 infection at the time of hospitalization, and potentially the viral load of the infected patient. Patients with erythrocyte aplasia or others with suspected EI or B19 infection should be presumed to have a B19 infection until proven otherwise. These patients should receive respiratory and contact isolation while hospitalized.

## ROUTES OF VIRAL SPREAD

Person-to-person spread of parvovirus B19 probably occurs through contact with respiratory secretions. Viral DNA is present in saliva [51,112,128,129] at levels similar to those in blood, and in a volunteer study infection was initiated by intranasal inoculation of B19 [51,130]. B19 cannot be detected in columnar epithelial cells of the large airways [131]. Indirect evidence suggests B19 is not transmitted by aerosols. Viruses transmitted by aerosols such as measles and influenza are rapidly spread during outbreaks, but new cases of EI are spread out over many months during school outbreaks, suggesting that B19 transmission is inefficient. B19 DNA may be found in the urine, but it is unlikely that this is associated with infectious virus.

The only well-documented route of spread for B19 is vertically from mother to fetus and from parenteral transfusion with contaminated blood products or needles. Vertical transmission is discussed later. Although transmission of B19 by transfusion occurs, it is rare because of the low prevalence of B19 viremia among donors of blood and blood products; however, the risk increases for pooled blood products [130–135]. B19 DNA is frequently found in clotting factor concentrates, including products treated with solvents and detergents, steam, or monoclonal antibodies, and even treated products may be infectious [95,133,135–138]. Seroprevalence of IgG antibodies to B19 is high among hemophiliacs compared with age-matched controls and is higher for individuals who received frequent infusions of clotting factors prepared from large donor pools compared with infusions prepared from small donor pools [134].

Parvoviruses are resistant to chemical inactivation. In one hospital, B19 transmission occurred without recognized direct patient contact, suggesting possible transmission via fomites or environmental contamination [116]. That B19 is transmitted by fomites has not been directly established, but, considering the stability of related animal parvoviruses, this possibility exists. B19 DNA, not infectious virus, was found in a study of a suspected nosocomial outbreak in a maternity ward [127]. B19 DNA was detected by polymerase chain reaction (PCR) on the hands of the mother of a stillborn fetus infected with B19 and on the sink handles in her hospital room. Samples from countertops, an intravenous pump, and telephone were also positive by a sensitive nested PCR DNA technique. PCR is so sensitive that minute quantities of DNA can be detected via this technique, and the presence of B19 DNA on surfaces does not imply that these surfaces are sources of infection. Infected fetal tissues and placental or amniotic fluids are more likely sources of infection for health care workers than fomites.

## RISK OF PARVOVIRUS B19 ACQUISITION FOR WOMEN OF CHILDBEARING AGE

We completed a large epidemiologic study to determine the relative risk of parvovirus B19 acquisition for women of childbearing age in daily contact with children, including nurses, day care employees, and teachers at all levels [21]. We identified risk factors for B19 infections for hospital and school employees during an endemic period. Serologic testing was employed to monitor 2730 employees of 135 schools in three school systems and 751 employees of a hospital, all in Richmond, Virginia. Of participants, 60% were initially seropositive. After adjusting for age, race, and gender, risk factors for seropositivity were contact with children 5 to 18 years old at home or at work and employment in elementary schools. Over 42 months, only 1 of 198 susceptible hospital employees seroconverted (0.42% annual rate) compared with 62 of 927 (2.93% annual rate) school employees (relative risk 6.9). Four factors associated with seroconversion were employment at elementary schools, contact with children 5 to 11 years old at home, contact with children 5 to 18 years old at work, and age younger than 30 years. Women in daily contact with school-age children had a fivefold increased annual occupational risk for B19 infection [21].

Several observations indicate that B19 infections were endemic, but not epidemic or pandemic in the Richmond area during the 42-month prospective evaluation [21]. First, few cases of B19 infection were reported by the school nurses, and no cluster of cases was observed at any single school or group of schools. Second, the

seroconversion rates during each of three consecutive study periods were the same for all groups or subgroups. Third, for employees, B19 infections were not clustered at individual schools or groups of schools. Fourth, the infection rates that we observed in employees, even for elementary school teachers, were less than those observed for the 1988 Connecticut epidemic, where 46 infections occurred among 236 susceptible individuals exposed in the schools, for a minimum annual infection rate of 19% [113]. Also, in a study of secondary B19 infections among exposed household members, rates ranged from 30% to 50% [102].

B19 infections are often asymptomatic or without a rash, and low-level endemics go unnoticed. We observed that 28 of 60 infected employees were asymptomatic, and only 20 knew of a specific exposure. In a study of 52 household contacts of patients with B19 infections during an Ohio epidemic, infections without a rash occurred in 15 of 16 (94%) African Americans and 17 of 35 (47%) whites, and completely asymptomatic infections occurred in 11 of 16 (69%) African Americans and 6 of 30 (20%) whites [102]. During the Connecticut outbreak, 5 of 65 (8%) teachers who were never exposed to a child with a rash became infected [113]. The observations of high secondary attack rates during epidemics and the high rates of infections without a rash or asymptomatic infections provide strong evidence that even during periods when EI is inapparent in the community, school or hospital personnel in contact with children have a significant occupational risk for B19 infections.

Contact with elementary school–age children, whether at home or at work, may be the most important risk factor for B19 acquisition. When seropositivity for persons with children at home was stratified by the child's age, the association between seropositivity and children at home was significant ($P < .05$) when all children 5 to 18 years of age were included; for seroconversion, the significant association was with elementary school–age children at home [21]. The low seroprevalence and seroconversion rate among hospital employees without known contact with children indicates that this group has a low occupational risk for acquiring B19 infections.

The major conclusions from these studies were that when EI is inapparent in the community, school or hospital personnel in contact with children still have a significant occupational risk for B19 infections, and that school employees have an approximately twofold greater risk of acquiring B19 from children at work than from elementary school–age children at home. We also found that hospital employees without contact with children have a low risk for acquiring B19.

Using the Richmond data and assuming that on average 50% of pregnant women are immune, we estimate that in endemic periods 1% to 4% of susceptible women become infected during pregnancy. If the rate of fetal death after maternal infection is 5% to 10% (see "Intrauterine Transmission Rates, Clinical Manifestations, and Fetal Outcomes"), the occupational risk of fetal death for a pregnant woman with unknown serologic status is between 1 in 500 and 1 in 4000 These rates are so low that during endemic periods they do not justify intervention, such as serologic testing for pregnant women or furloughing or temporary transfer of pregnant seronegative employees to administrative or other positions without child contact (see "Prevention").

Knowing B19 infection rates during endemic periods may be more important than knowing rates during epidemic periods. In the United States, B19 infections are endemic most of the time. Because greater than 75% of B19 infections are inapparent, most women who acquire B19 infection during pregnancy do so during endemic periods, not during epidemics. For establishing public health policy and assessing the potential importance of immunizing against B19, knowing that for seronegative women the endemic infection rate is 1% to 4% is more important than knowing epidemic rates, which vary widely depending on the frequency of susceptible individuals in a given population at a particular time.

## CLINICAL MANIFESTATIONS (OTHER THAN INTRAUTERINE INFECTION)

### ERYTHEMA INFECTIOSUM

The most common clinical manifestation of infection with parvovirus B19 is EI, or fifth disease, a well-known rash illness of children. EI begins with a mild prodromal illness consisting of low-grade fever, headache, malaise, and upper respiratory tract symptoms. This prodrome may be so mild as to go unnoticed. The hallmark of the illness is the characteristic exanthem. The rash usually occurs in three phases, but these are not always distinguishable [12,106,139]. The initial stage consists of an erythematous facial flushing described as a "slapped-cheek" appearance. In the second stage, the rash spreads quickly to the trunk and proximal extremities as a diffuse macular erythema. The third stage is central clearing of macular lesions, which occurs promptly, giving the rash a lacy, reticulated appearance. Palms and soles are usually spared, and the rash tends to be more prominent on the extensor surfaces. Affected children at this point are afebrile and feel well. Adolescents and adults often complain of pruritus or arthralgias concurrent with the rash. The rash resolves spontaneously, but typically may recur over 1 to 3 weeks in response to various environmental stimuli, such as sunlight, heat, exercise, and stress [140].

Lymphadenopathy is not a consistent feature, but has been reported in association with EI [101] and as a sole manifestation of infection [141–143]. A mononucleosis-like illness associated with confirmed B19 infections has occasionally been reported, but B19 does not typically cause a mononucleosis-like illness. Atypical rashes not recognizable as classic EI have also been associated with acute B19 infections; these include morbilliform, vesiculopustular, desquamative, petechial, and purpuric rashes [4].

Asymptomatic infection with B19 also occurs commonly in children and adults. In studies of large outbreaks, asymptomatic infection is reported in approximately 20% to 30% of serologically proven cases [101,102].

### TRANSIENT APLASTIC CRISIS

As noted earlier, transient aplastic crisis was the first clinical illness to be definitively linked to infection with parvovirus B19. An infectious etiology had been suspected for this condition because it usually occurred only once

in a given patient, had a well-defined course and duration of illness, and tended to occur in clusters within families and communities [140]. Attempts to link it to infection with any particular agent had repeatedly failed until 1981, when Pattison and colleagues [8] reported six positive tests for B19 (seroconversion or antigenemia) among 600 admissions to a London hospital—all six positive tests were in children with sickle cell anemia admitted with aplastic crisis. This association was confirmed by studies of an outbreak of aplastic crisis in the population with sickle cell disease in Jamaica [9].

Although such transient aplastic crises are most commonly associated with sickle cell anemia, any patient with a condition of increased red blood cell turnover and accelerated erythropoiesis can experience a similar transient red blood cell aplasia with B19 infection. B19-induced aplastic crises have been described in many hematologic disorders, including other hemoglobinopathies (e.g., thalassemia, sickle-C hemoglobin), red blood cell membrane defects (e.g., hereditary spherocytosis, stomatocytosis), enzyme deficiencies (e.g., pyruvate kinase deficiency, glucose-6-phosphate dehydrogenase deficiency), antibody-mediated red blood cell destruction (autoimmune hemolytic anemia), and decreased red blood cell production (e.g., iron deficiency, blood loss) [49,144]. B19 is not a significant cause of transient erythroblastopenia of childhood, another condition of transient red blood cell hypoplasia that usually occurs in younger, hematologically normal children and follows a more indolent course [4].

In contrast to EI, patients with a transient aplastic crisis are ill at presentation with fever, malaise, and signs and symptoms of profound anemia (e.g., pallor, tachypnea, tachycardia). Rash is rarely present in these patients [104,144]. The acute infection causes a transient arrest of erythropoiesis (see "General Aspects of Pathogenesis") with a profound reticulocytopenia. Given the short half-life of red blood cells in these patients and their dependence on active erythropoiesis to counterbalance their increased red blood cell turnover, this arrest of erythropoiesis leads to a sudden and potentially life-threatening decrease in serum hemoglobin. Children with sickle hemoglobinopathies may also develop a concurrent vaso-occlusive pain crisis, which may complicate the clinical picture further.

Leukopenia and thrombocytopenia may also occur during a transient aplastic crisis, but the incidence varies with the underlying condition. In a French study of 24 episodes of aplastic crisis (mostly in individuals with hereditary spherocytosis), 35% to 40% of patients were either leukopenic or thrombocytopenic compared with 10% to 15% reported in a large U.S. study of mostly sickle cell patients [104,145]. These transient declines in leukocyte count or platelets follow a similar time course as reticulocytopenia, although they are not as severe, and recovery occurs without clinical sequelae. The relative preservation of leukocyte and platelet counts in sickle cell anemia compared with other hereditary hemolytic anemias is presumably due to the functional asplenia associated with sickle cell disease [49].

As noted in experimental infection in human volunteers, B19 infection in normal subjects results in a decrease in the reticulocyte count, but owing to the normal red blood cell half-life, this is not clinically significant or noticeable. Varying degrees of leukopenia and thrombocytopenia also occur after natural B19 infection in hematologically normal patients [51]. Some cases of idiopathic thrombocytopenic purpura and cases of childhood neutropenia have been reported in association with acute B19 infection [146,147]. Aside from these few anecdotal reports, larger studies have not confirmed B19 as a common cause of either idiopathic thrombocytopenic purpura or chronic neutropenia in children [48].

## ARTHROPATHY

Joint symptoms are reported by 80% of adolescents and adults with parvovirus B19 infection, whereas joint symptoms are uncommon in children [12,106]. Arthritis or arthralgia may occur in association with the symptoms of typical EI or may be the only manifestation of infection. Women are more frequently affected with joint symptoms than men [12,106].

The joint symptoms of B19 infection usually manifest as the sudden onset of a symmetric peripheral polyarthropathy [148]. The joints most often affected are the hands, wrists, knees, and ankles, but the larger joints can also be involved [110,149]. The joint symptoms have a wide range of severity, from mild morning stiffness to frank arthritis with the classic combination of erythema, warmth, tenderness and swelling. Similar to the rash of EI, the arthropathy has been presumed to be immunologically mediated because the onset of joint symptoms occurs after the peak of viremia and coincides with the development of specific IgM and IgG antibodies [51]. Rheumatoid factor may also be transiently positive, leading to some diagnostic confusion with rheumatoid arthritis in adult patients [150]. There is no joint destruction, and in most patients joint symptoms resolve within 2 to 4 weeks. For some patients, joint discomfort may last for months or, in rare individuals, years. The role of B19 in these more chronic arthropathies is unclear.

The arthritis associated with B19 infection may persist long enough to satisfy clinical diagnostic criteria for rheumatoid arthritis or juvenile rheumatoid arthritis [89,97,149,151,152]. This finding has led some authors to suggest that B19 may be the etiologic agent of these conditions [5]. This speculation has been supported by the detection of B19 DNA in synovial tissue from patients with rheumatoid arthritis and reports of increased seropositivity among patients with these conditions [98,153–155]. The more recent findings of DNA from other viruses in addition to B19 in synovial tissue from patients with arthritis and B19 DNA in synovium from persons without arthritis suggest that this may be a nonspecific effect of inflammation [156,157]. A review of the accumulated evidence on this topic has concluded that B19 is unlikely to be a primary etiology in these rheumatic diseases, but it may be one of several viral triggers capable of initiating joint disease in genetically predisposed individuals [158].

## INFECTION IN IMMUNOCOMPROMISED HOSTS

Patients with impaired humoral immunity are at risk for developing chronic and recurrent infections with parvovirus B19. Persistent anemia, sometimes profound, with

reticulocytopenia is the most common manifestation of such infections, which may also be accompanied by neutropenia, thrombocytopenia, or complete marrow suppression. Chronic infections with B19 occur in children with cancer who receive cytotoxic chemotherapy [159,160], children with congenital immunodeficiency states [161], children and adults with acquired immunodeficiency syndrome (AIDS) [162], and transplant recipients [163]. Chronic infections may even occur in patients with more subtle defects in immunoglobulin production, who are able to produce measurable antibodies to B19, but are unable to generate adequate neutralizing antibodies [164].

B19 has also been linked to viral-associated hemophagocytic syndrome [159,160], more generally referred to as infection-associated hemophagocytic syndrome. This condition of histiocytic infiltration of bone marrow and associated cytopenias usually occurs in immunocompromised patients. B19 is only one of several viruses that have been implicated as causing viral-associated hemophagocytic syndrome. Infection-associated hemophagocytic syndrome is generally considered to be a nonspecific response to various viral and bacterial insults, rather than a specific manifestation of a single pathogen.

Infections in immunocompromised hosts can lead to chronic infection; this is most often manifested as chronic anemia (red blood cell aplasia), but varying degrees of cytopenia have been described, ranging from thrombocytopenia or neutropenia to complete bone marrow failure [144]. Patients with an inability to produce neutralizing antibodies are at greatest risk, and this complication of B19 infection has been described in children with congenital immunodeficiency syndromes, patients receiving cytoreductive chemotherapy, transplant patients receiving immunosuppressive therapy, and adults and children with AIDS [144]. Increased recognition of B19 infection in solid organ transplant patients has led to many more recent reports [165–167]. Although most such infections are manifested as the typical persistent anemia, an association of B19 viremia with acute graft rejection has been described [168].

## OTHER DERMATOLOGIC SYNDROMES

### Vasculitis and Purpura

Various atypical skin eruptions have been described in association with parvovirus B19 infections. Most of these are petechial or purpuric in nature, often with evidence of vasculitis in descriptions of eruptions that report skin biopsy results, and may resemble the rash of other connective tissue diseases [4,169]. There are reports of confirmed acute B19 infections associated with nonthrombocytopenic purpura and vasculitis, including several cases clinically diagnosed as Henoch-Schönlein purpura [90,170], an acute leukocytoclastic vasculitis of unknown etiology in children. Chronic B19 infection has also been associated with a necrotizing vasculitis, including cases of polyarteritis nodosa and Wegener granulomatosis [171]. These patients had no underlying hematologic disorder and were generally not anemic at diagnosis. The pathogenesis is unknown, but could suggest an endothelial cell infection as occurs with some other viruses such as rubella.

Data from skin biopsy of rashes temporally associated with B19 infection are limited, although several reports have been published. B19 capsid antigens and DNA were found in a skin biopsy specimen from a patient with EI, and this observation lends support to a role for B19 in these vascular disorders [172]. Rashes resembling those of systemic lupus erythematosus, Henoch-Schönlein purpura, and other connective tissue disorders have been described [169,173]. In a controlled study of 27 children with Henoch-Schönlein purpura, B19 was not a common cause [174]. Only 3 of 27 children had detectable B19 IgM antibodies indicating a recent infection. The role of B19 in these conditions remains speculative.

### Papular-Purpuric "Gloves and Socks" Syndrome

Papular-purpuric "gloves and socks" syndrome (PPGSS) is a distinctive, self-limited dermatosis first described in the dermatologic literature in 1990 [175]. PPGSS is characterized by fever, pruritus, and painful edema and erythema localized to the distal extremities in a distinct glove-and-sock distribution. The distal erythema is usually followed by petechiae or papules or purpura, and oral lesions often develop as well. Resolution of all symptoms usually occurs in 1 to 2 weeks. A search for serologic evidence of viral infection led to the discovery of an association with acute parvovirus B19 infection in many of these patients, based on demonstration of specific IgM or seroconversion. This association has been confirmed further with subsequent reports and demonstration of B19 DNA in skin biopsy samples and sera from these patients [175,176]. Initially described in adults, numerous children have now been described with this condition [177]. There seems to be sufficient evidence to suggest that PPGSS is a rare but distinctive manifestation of primary, acute infection with B19, occurring mainly in young adults, but also affecting children.

## CENTRAL NERVOUS SYSTEM INFECTION AND NEUROLOGIC DISORDERS

Although various neurologic symptoms and disorders have been described in patients clinically diagnosed as having EI or laboratory-confirmed parvovirus B19 infection [4], the issue of whether B19 causes central nervous system (CNS) infection or is etiologic for other neurologic conditions remains unresolved. Cases of meningitis [178,179], encephalitis [180], and encephalopathy [181] secondary to B19 infection all have been reported. Many of these cases were reported during outbreaks of EI from older reports based on clinical diagnosis only, before reliable laboratory tests for B19 were available. In one study, headache was reported in 32% of children with rash illness [178].

There are no controlled comparative studies to evaluate the frequency of signs or symptoms suggestive of meningeal inflammation or CNS infection in B19 infection. Cerebrospinal fluid abnormalities such as pleocytosis and increased levels of cerebrospinal fluid protein have been reported in some, but not all, patients with meningismus or altered level of consciousness associated with EI [5]. B19 DNA has been detected in cerebrospinal fluid

using PCR in several cases of serologically confirmed acute B19 infection with meningoencephalitis or encephalopathy [182–184]. Most of these reported patients were also viremic at the time, however, so the possibility that cerebrospinal fluid PCR was positive secondary to contamination from blood could not be completely excluded.

B19 infection has been associated with vasculitis and histopathologic changes in the CNS that potentially may lead to stroke [339]. Most cases of stroke in association with documented B19 infection have been reported in children; some of these children have had other concurrent medical conditions that could contribute to stroke, particularly sickle cell disease [340–342]. At least two cases of neonatal stroke have been reported in association with B19 infection: one related to maternal infection during gestation and the other associated with infection of the newborn infant [343,344].

Disorders of the peripheral nervous system have also been described, including brachial plexus neuropathy [185], carpal tunnel syndrome [188], extremity paresthesias and dysesthesias [186], and myasthenia-like weakness [187]. The onset of most of these peripheral nerve symptoms has been coincident with the onset of rash or joint pain or both at a time when the patient should have a brisk immune response, suggesting that the neurologic abnormalities could be immunologically mediated [5]. In the course of one well-described outbreak of EI among intensive care nurses, numbness and tingling of the fingers was reported in 54% of the 13 nurses infected with B19 [186]. The neurologic symptoms persisted for more than 1 year in three of the nurses, and one had low levels of B19 DNA in serum for more than 3 years in association with recurrent episodes of paresthesias. She was never anemic and had no demonstrable immunodeficiency [189]. Although these cases are suggestive, the role of B19 in neurologic disease, stroke, and CNS infection remains unresolved until the pathogenesis of the viral infection in these conditions can be elucidated [5,190].

## RENAL DISEASE

Reports of renal disease after parvovirus B19 infection, previously rare, have increased [191–193]. Most have been case reports of glomerulonephritis or focal glomerulosclerosis temporally related to an acute B19 infection. Immune complex deposition has been shown in renal tissue, and B19 DNA can occasionally be found in renal tissue by PCR as well [194]. Renal failure is rarely reported. The virus is not known to infect kidney cells in vitro, and its presence in renal tissue could be secondary to filtration from the viremia of acute infection. B19 DNA has been detected in urine in studies of infants with evidence of intrauterine infections. It is possible that B19 antigens could trigger an immune complex–mediated nephritis, but this may be a nonspecific effect, and further study is necessary to define the relationship between B19 infection and the potential for renal disease.

## MYOCARDIAL DISEASE

Parvovirus B19 is now a well-established, although infrequent, cause of myocarditis in children and adults. B19 DNA is often present within the myocardium of patients with myocarditis and idiopathic left ventricular failure [195–200]. B19 infection has also been associated with acute dilated cardiopathy, but the etiologic significance of B19 in the myocardium is unclear [201]. Myocarditis resulting from B19 infection usually resolves over several weeks, but is occasionally fatal [202–204].

# GENERAL ASPECTS OF DIAGNOSIS

The diagnosis of EI (fifth disease) is usually based on the clinical recognition of the typical exanthem, benign course, and exclusion of other similar conditions. Laboratory confirmation is rarely necessary. A presumptive diagnosis of a parvovirus B19–induced transient aplastic crisis in a patient with known sickle cell disease (or other condition associated with chronic hemolysis) is based on an acute febrile illness, a sudden and severe decline in serum hemoglobin, and an absolute reticulocytopenia. Likewise, a clinical diagnosis of PPGSS can be based on the characteristic skin eruption in the distinct acral distribution.

## LABORATORY DIAGNOSTIC METHODS

Specific laboratory diagnosis depends on identification of parvovirus B19 antibodies, viral antigens, or viral DNA. In an immunologically normal patient, determination of anti-B19 IgM is the best marker of recent or acute infection on a single serum sample. IgM antibodies develop rapidly after infection and are detectable for 6 to 8 weeks [205]. Specific IgG antibodies become detectable a few days after IgM and persist for years and probably for life. Seroconversion from IgG-negative to IgG-positive on paired acute and convalescent sera confirms a recent infection. Anti-B19 IgG primarily serves as a marker of past infection or immunity, however. Patients with EI or acute B19 arthropathy are almost always IgM-positive, so a diagnosis can generally be made from a single serum sample. Patients with B19-induced aplastic crisis may present before antibodies are detectable; however, IgM is detectable within 1 to 2 days of presentation, and detection of IgG follows within days [104].

The availability of serologic assays for B19 had previously been limited by the lack of a reliable and renewable source of antigen for diagnostic studies. The development of recombinant cell lines that express B19 capsid proteins has provided more reliable sources of antigen suitable for use in commercial test kits [206,207]. Several commercial kits are currently available for detection of B19 antibodies, but they employ a variety of different antigens (e.g., recombinant capsid proteins, fusion proteins, synthetic peptides), and their performance in large studies has varied [206]. Based on studies of the humoral immune response to the various B19 viral antigens, it seems to be important to have serologic assays based on intact capsids that provide conformational epitopes. Antibody responses to these antigens are more reliable and longer lasting than the responses to linear epitopes used in some assays [208].

At present, only one commercial assay based on such capsids has received approval from the U.S. Food and Drug Administration (FDA); other commercial assays for this purpose are considered research tests [209]. Until serologic tests are more standardized and results are more

consistent, some knowledge of the assay and antigens used is necessary for proper interpretation of B19 antibody test results.

In immunocompromised or immunodeficient patients, serologic diagnosis is unreliable because humoral responses are impaired, so methods to detect viral particles or viral DNA are necessary to make the diagnosis of a B19 infection. As noted, the virus cannot be isolated on routine cell cultures, so viral culture is not useful. Detection of viral DNA by DNA hybridization techniques [210] or by PCR [211,212] is useful in these patients. Both techniques can be applied to various clinical specimens, including serum, amniotic fluid, fresh tissues, bone marrow, and paraffin-embedded tissues [148]. Histologic examination is also helpful in diagnosing B19 infection in certain situations. Examination of bone marrow aspirates in anemic patients typically reveals giant pronormoblasts or "lantern cells" against a background of general erythroid hypoplasia. The absence of such cells does not exclude B19 infection, however [213,214]. Electron microscopy has proven useful and may reveal viral particles in serum of some infected patients and in cord blood or tissues of hydropic infants (see "Pathogenesis of Infection in the Fetus").

## EPIDEMIOLOGY OF PARVOVIRUS B19 INFECTIONS AND RISK OF ACQUISITION IN PREGNANT WOMEN

### PREVALENCE AND INCIDENCE IN THE UNITED STATES

We completed three studies using complementary strategies to determine the incidence of parvovirus B19 infection during pregnancy. First, using the data from a study of school personnel, we estimated the average B19 infection rate among pregnant school personnel [21]. Of the 60 individuals who seroconverted in that study, 8 (13%) were pregnant. Not all pregnant women in the school system participated in the study. Although we had data on the pregnancy rates for the female school personnel who participated, these volunteers may have been biased toward younger women, raising the possibility that their pregnancy rates may not have been representative of all school employees. Of approximately 11,637 total school employees in Richmond, Virginia, we enrolled 2730 (24%) in our study. To determine if the sample enrolled was representative, we performed a random survey of 733 school employees at the schools studied. The results provided strong evidence that the seroprevalence and annual infection rates observed among study subjects were representative and applicable to the entire school employee population [21]. Assuming no seasonality to B19 infections, as none was observed, and that pregnancy does not affect susceptibility, we predicted that without regard to risk factors, seronegative pregnant personnel have an average annual infection rate of 3%, for a rate of 2.25% per pregnancy [21].

Second, in Richmond, Virginia, from 1989–1991, we collected sera from 1650 pregnant women from a lower socioeconomic group, who attended a high-risk pregnancy clinic for patients without medical insurance. This group was 80% African American with an average maternal age of 24 years. We randomly selected a subset of 395 women for serologic testing and monitoring, 35% of whom were seropositive. Of the 256 seronegative women, 2 (0.8%) seroconverted for an annual rate of 1.7%. This rate was similar to the rate observed among low-risk African American school personnel in Richmond [21].

Finally, we also obtained serial sera from a large group of private practice obstetric patients from Birmingham, Alabama [215]. From this serum bank, we randomly selected 200 patients per year over 4 years, 1987–1990. No significant differences in seroprevalence were observed by year among the 800 patients (average age 27 years and 88% white), and 46% were seropositive overall. Of 413 seronegative women serially tested over the 4 years, 5 seroconverted. Overall, the annual seroconversion rate was 2%. Combining data from the studies of pregnant women done in Richmond and Birmingham, we observed that 7 of 669 seronegative women seroconverted in pregnancy for a rate of 1% per pregnancy with a 95% confidence interval of 0.3% to 21%.

### PREVALENCE AND INCIDENCE IN OTHER COUNTRIES

In numerous studies conducted worldwide, including pregnant women and women of reproductive age, the seroprevalence of IgG antibodies to parvovirus B19 has ranged from 16% to 81%, with most estimates between 35% and 55% [73,78,79,88,216–219]. In Denmark, a serologic survey of 31,000 pregnant Danish women found 65% had evidence of past infection [105]. The seroprevalence of IgG antibody among 1610 pregnant women in Barcelona was 35.03% [22]. Of pregnant Swedish women, 81% had parvovirus antibodies [220]. In Japan, the seroprevalence of IgG antibodies to B19 was 26% for women 21 to 30 years old and 44% for women 31 to 40 years old [78]. In Germany, 62.9% of 40,517 pregnant women had IgG antibodies to B19 [218]. The prevalence of IgG antibodies to B19 in cord blood from normal newborns also provides estimates of maternal immunity of 50% to 75% [19,221,222].

Without regard to maternal age or other potential risk factors, a South African study found that 64 (3.3%) of 1967 pregnant women acquired B19 infection during pregnancy, and another study in Barcelona found that 60 (3.7%) of 1610 pregnant women became infected with B19 during pregnancy [22,223]. Seroconversion rates among susceptible pregnant Danish women during endemic and epidemic periods were 1.5% and 13%. In Denmark, risk of infection increased with the number of children in the household, and having children ages 6 to 7 years resulted in the highest rate of seroconversion. Nursery school teachers had a threefold increased risk of acute infection [105]. Extrapolating to a 40-week period would place the infection rate during pregnancy among susceptible women at approximately 1.1%, with a range of 1% to 4% depending on risk factors. The Danish and Barcelona data are similar to data obtained in Richmond, Virginia [21].

A prospective study conducted from 1998–2000 of 2567 pregnant women found that 70% had IgG antibodies to B19 at the beginning of pregnancy, and of those

seronegative, 2.4% acquired B19 during pregnancy [216]. A similar study of 13,449 women conducted in five European countries found that the risk of a seronegative woman acquiring B19 during pregnancy ranged from 0.61% in Belgium to 1.58% in Poland [217].

A few studies have tried to estimate the infection rate based on the prevalence of IgM antibodies to B19 in pregnancy or in women of reproductive age. Although B19-specific IgM is an accurate diagnostic test for recent infection, it is a poor test for epidemiology studies. B19 IgM persists for only a few months and underestimates the maternal infection rate because women who have had a B19 infection 6 to 9 months before testing would not be detected by this assay. Another problem with IgM surveys is that most studies have surveyed high-risk populations, such as women with rash illness, possible exposure to cases of EI, or recent diagnosis of adverse reproductive outcomes. Sampling high-risk populations biases the results toward rates higher than would be observed in population-based studies. A few studies have used B19-specific IgM to test pregnant women or women of reproductive age who did not have risk factors for infection. The observed range in these studies was 0 to 2.6% [19,221,224]. For susceptible women of reproductive age in populations known to be at increased risk for infection, the prevalence of IgM has ranged from 0 and 12.5% [19,78,128,225,226].

In countries other than the United States, the prevalence of IgG antibodies to B19 among pregnant women and women of reproductive age varies widely and is likely to reflect exposure during prior epidemics. Studies on infections during pregnancy are fraught with potentially confounding variables, such as use of IgM testing, which lacks sensitivity, and selection bias introduced by selection criteria for the population studied. Despite these problems, it is likely the risk for B19 infection during pregnancy in other countries is similar to that observed in the United States.

## CLINICAL MANIFESTATIONS OF PARVOVIRUS B19 INFECTIONS IN PREGNANT WOMEN

The symptoms reported by pregnant women with a proven recent parvovirus B19 infection are usually vague and nonspecific, so serologic confirmation is essential to establish the diagnosis. The signs and symptoms of classic EI in children are significantly different in adults; the sunburned or slapped-cheek facial rash common in children rarely occurs in adults. Malaise is a common feature of B19 infection in children and in adults, but is nonspecific. In pregnant women and adolescents, the most characteristic symptom is symmetric arthralgias, occasionally with signs of arthritis, and usually involving the small distal joints of hands, wrists, and feet.

The proportion of pregnant women with serologically proven B19 infection who are asymptomatic varies with the inclusion criteria in the few studies that address symptoms. In a cohort of 1610 pregnant women studied in Barcelona, the sera of 30 women had IgM antibodies to B19 at the first prenatal visit, and another 30 seroconverted during pregnancy [22]. Of these 60 women, only 18 (30%) reported any combination of fever, rash, and arthralgias—70% were asymptomatic. The authors did not report when questions about symptoms were asked in relation to the serologic results, and no comment was made about the distribution of symptoms or about which joints were affected by the arthralgias [22]. Similarly, during an epidemic of EI in Connecticut, 69% of nonpregnant adults with serologically proven B19 infection were asymptomatic. In this study, symptoms were assessed by mailed questionnaires after the women were provided their serologic results [113,127]. In a British multicenter study, only 6 (3%) of 184 patients were asymptomatic, but the population was ascertained largely by recruiting women with typical symptoms, so this study is not comparable to the others [20].

We studied 618 pregnant women in Pittsburgh, Pennsylvania, with known exposure to someone with a rash illness highly suggestive of EI. Each exposed patient was questioned about symptoms before serologic testing. Only 33% of the 52 women with serologically proven B19 infection reported no symptoms, whereas the remaining 67% reported rash, fever, arthralgias, coryza, or malaise [227]. Malaise, although a very vague and nonspecific finding, was reported by 27 (52%) of the 52 infected women [227]. In contrast, only 5.5% of 307 exposed, but not susceptible (IgG seropositive, IgM seronegative), women reported this symptom. After malaise, symmetric arthralgias were the second most common symptom reported. Of the 618 pregnant women with known exposures, 24 (46%) of the 52 infected pregnant women reported arthralgias compared with 11 (3.6%) of 307 immune women and 12 (4.6%) of 259 susceptible, but uninfected women ($P < .0001$) [227]. Of the 24 women with arthralgias in this study, 23 also reported malaise, 16 reported rash, 7 reported coryza, and 7 reported fever. Among the 24 IgM-positive women with arthralgias, the symmetric joints most commonly affected by pain, swelling, and erythema were the knees (75%) followed by wrists (71%), fingers (63%), ankles (42%), feet (29%), elbows (29%), shoulders (17%), hips (13%), and back and neck (8%). Only 2 of the 24 women had only one set of joints involved, and very few other women reported monarticular pain or swelling. In most women, the arthralgias were easily controlled by anti-inflammatory drugs and lasted only 1 to 5 days. Arthralgias occasionally lasted 10 to 14 days, however, and in some women were so painful that they were incapacitated for 2 to 3 days.

The high frequency of arthralgia in pregnant women with B19 infection is consistent with reports that distal arthralgias and arthritis are the most frequent finding in adults with EI. The frequency of arthralgias among nonpregnant adults with proven B19 infection in the Torrington, Connecticut, epidemic was 24% (11 of 46 adults) compared with 12% (61 of 512 adults) in adults without B19 infection ($P < .05$) [113]. In another study in Connecticut, arthralgias occurred significantly more often (26%) in 19 adults with IgM antibodies to B19 than in 460 adults (7%) who lacked IgM antibodies to B19 ($P < .01$) [127]. Arthralgias were even more common during outbreaks in Ireland, occurring in 79% of 47 recently infected women and men. Of patients with arthralgias, 93% reported that their knees were involved [228].

Rash is less frequent in pregnant women than in children with EI, and the rash in pregnant women is not characteristic. In one report of the Connecticut epidemic, rashes occurred in 6 (13%) of 46 infected adults compared with 49 (10%) of 512 individuals who were uninfected. In another report, rashes occurred in 3 (16%) of 19 infected adults compared with 33 (7%) of 460 uninfected individuals. This difference was not significant ($P = .16$) and may represent random variation [113]. In contrast to the classic "curtain lace" rash in children, pregnant women (80%) often have a maculopapular rash that rarely involves the face and may be urticarial or morbilliform. In adults, these rashes are rarely pruritic and usually resolve within 1 to 5 days. A Japanese study reported that of 100 pregnant women with a confirmed B19 infection during pregnancy, 51 had a facial, body, or limb rash, and 49 were without symptoms [229]. In the Pittsburgh, Pennsylvania, series, coryza was reported by 23% of the 52 B19-infected pregnant women, but was reported in only 6.8% of the 307 previously infected women, and 5.8% of the 259 seronegative women [227]. This difference was significant ($P < .0001$), but the nonspecific nature of coryza in pregnant women means this symptom alone is not diagnostically helpful.

In the Pittsburgh, Pennsylvania, series, a temperature 38° C or greater occurred in 19% of 52 IgM-seropositive, B19-infected women compared with 2.6% of 307 previously infected patients and 3.1% of 259 susceptible, noninfected patients ($P < .0001$) [227]. In 9 of 10 women with fever, at least one other symptom was present. No woman's temperature exceeded 38.9° C. In 16 uninfected women with fever, all had at least one other symptom, and temperatures ranged up to 40° C, suggesting that a temperature greater than 39° C in a pregnant woman indicates infections other than B19. In a London outbreak of B19 infection, 7 of the 10 infected adults had an elevated temperature [117]. In the Connecticut epidemic, fever was reported in 15% of the 46 infected individuals, but also in 16% of the 512 uninfected individuals [113]. Occasionally, pregnant women infected with B19 develop rapidly increasing fundal height, preterm labor, or preeclampsia. Such symptoms are nonspecific and rarely indicate B19 infection.

# INTRAUTERINE TRANSMISSION RATES, CLINICAL MANIFESTATIONS, AND FETAL OUTCOMES

## OVERVIEW

Primary maternal infection with parvovirus B19 during gestation has been associated with adverse outcomes, such as nonimmune hydrops fetalis, intrauterine fetal death, and asymptomatic neonatal infection, but also with normal delivery at term [16,17]. Initial reports of fetal hydrops related to maternal B19 infection were anecdotal and retrospective, suggesting rates of adverse outcomes of 26% and generating concern that B19 might be more fetotropic than rubella or CMV [230,231]. Subsequent reports of normal births after documented maternal B19 infection made clear the need for better estimates of the rate of intrauterine transmission and the risk of adverse outcomes [232,233].

## FETAL DEATH

Parvovirus B19 was first linked to fetal death in 1984 [17]. As anticipated based on the epidemiology of B19 transmission, the percentage of all fetal deaths attributable to B19 varies probably depended on the frequency of B19 infections in the population being studied. Overall, the contribution of B19 infection to fetal death is variable.

Prospective studies report rates of intrauterine viral transmission ranging from 25% to 50% [20,234,235]. Initial studies indicated that the risk of an adverse fetal outcome after a recent maternal infection is less than 10% and probably much less, with greatest risk in the first 20 weeks of pregnancy [148]. A large British prospective study identified 186 pregnant women with confirmed B19 infections during an epidemic and followed these women to term [20]. There were 30 (16%) fetal deaths in all, with 17 (9%) estimated to be due to B19 on the basis of DNA studies of a sample of the abortuses. Most of the fetal deaths occurred in the first 20 weeks of gestation with an excess fetal loss in the second trimester [20]. The intrauterine transmission rate was estimated at 33% based on analysis of the abortuses, fetal IgM in cord blood, and persistence of B19 IgG at 1-year follow-up of the infants. A smaller study of 39 pregnancies complicated by maternal B19 infection and followed to term found two fetal deaths (fetal loss rate of 5%), one (3%) of which was attributable to B19 and occurred at 10 weeks' gestation [234].

A prospective study conducted by the U.S. Centers for Disease Control and Prevention (CDC) identified 187 pregnant women with B19 infection and compared their outcomes with 753 matched controls [235]. The overall fetal loss rate in the infected group was 5.9% with 10 of 11 occurring before the 18th week of gestation compared with 3.5% fetal loss rate in the control group, suggesting a fetal loss rate of 2.5% attributable to B19. In a prospective Spanish study during an endemic period, 1610 pregnant women were screened for B19 infection, and 60 (3.7%) were identified [22]. There were five abortions among this group, but only one (1.7%) was caused by B19 based on histologic and virologic analysis of fetal samples. The incidence of vertical transmission was estimated at 25% based on serologic evaluation of the infants at delivery and at 1 year of age. In a similar prospective study of an obstetric population, 1967 pregnant women were screened, and 64 (3.3%) were identified as recently infected [223]. Among this group, no adverse effects were seen by serial ultrasound examinations, and no fetal hydrops was noted; one abortion occurred, but the fetus was not examined for evidence of B19 infection (maximal fetal loss attributable, 1.6%).

In a Japanese study of 100 women with a confirmed B19 infection during pregnancy, the fetal loss rate including hydrops and fetal death was 7% with all maternal infections occurring before the 20th week of gestation [229]. These results are similar to results from a larger study from Germany, where 1018 pregnant women with a confirmed B19 infection during pregnancy were studied [236]. The overall fetal death rate was 6.3%, with the highest death rate (11%) occurring among women infected before 20 weeks of gestation. The overall rate of hydrops was 3.9% [236]. In a case-control study of

192 women with fetal deaths, half occurring before 20 weeks' gestation and half after, there was serologic evidence of acute B19 infection in 1% of case and control groups [19]. The prevalence of IgG antibodies was also similar. In this study, the percentage of fetal deaths attributed to B19 infection was unlikely to exceed 3% in cases not selected for parvovirus exposure.

In another study, 5 (6.3%) of 80 women with spontaneous abortions between 4 and 17 weeks of gestation had IgM antibodies to B19 compared with 2 (2%) of 100 controls, but this difference was not statistically significant [226]. Additionally, these investigators studied the aborted fetuses from the five seropositive cases and found B19 DNA in only two.

In a prospective study of 39 pregnant women infected with B19 during a community-wide outbreak in Connecticut, there were two fetal deaths, and only one (3%) was attributable to B19 infection [234]. Among women followed prospectively and who acquired B19 infection during pregnancy, there was no evidence of fetal damage in 43 in Richmond, Virginia, and 52 in Pittsburgh, Pennsylvania, and one fetal loss among 56 pregnancies in women from Barcelona [22,23,227].

Two Chinese studies found fetal B19 infection frequently associated with fetal death [237,238]. The first study in China found that of 116 spontaneously aborted fetuses tested for B19 DNA, 27.3% were positive for parvovirus B19, but only 4% (1 of 25) of nonaborted fetal tissues in the control group tested positive [237]. This difference was significant. It was unknown when these samples were collected, or whether B19 was endemic or epidemic in the community. The second Chinese study examined 175 biopsy tissues from spontaneous abortions from 1994–1995 and found that 25% were positive for B19 DNA in the fetal tissues [238]. A control group of 20 fetal tissues came from induced abortions, and only 2 (5%) were positive. This difference was not statistically significant, but did support the observation that in China, B19 may be an important cause of fetal death, especially if B19 is epidemic in the community.

In contrast to the Chinese studies, a study from the Netherlands of fetal and placental tissue from 273 cases of first-trimester and second-trimester fetal loss were tested for serologic or virologic evidence of B19 infection [239]. Of the 273 cases, 149 were from seronegative women, and the fetal deaths for these women were considered unrelated to B19. The mothers had IgM antibodies to B19 at the time of abortion in only 2 of the remaining 124 cases (0.7% for all 273 cases). This study indicates that B19 infection was a rare cause of fetal loss during the first and second trimesters. No congenital anomalies were observed among the fetal tissues examined.

In a study of 1047 pregnant women in Kuwait, maternal blood samples were obtained in the first, second, and third trimesters and tested for serologic evidence of recent B19 infection [240]. Of the mothers, 47% were seronegative, and in these women the incidence of seroconversion was 16.5%. Among the women who seroconverted to B19, the rate of fetal loss was 5.4%. All the fetal deaths occurred in the first two trimesters, suggesting that fetal death after maternal B19 infection is common, particularly during the first and second trimesters.

A report from Toledo, Ohio, described five unexpected fetal deaths that occurred in the second trimester [241]. Only one of the fetuses was hydropic, but all five contained viral inclusions in the liver, and all five women were seropositive to B19.

Fetal deaths in the third trimester have also been reported (Table 27–2). A Swedish study of fetal deaths among 33,759 pregnancies found 93 cases of third-trimester fetal deaths, and of these, 7 (7.5%) had detectable B19 DNA in frozen placental tissue [242]. None of the seven fetuses was hydropic. The authors suggested B19 occasionally caused fetal death in the third trimester.

A study of 13 pregnant women who acquired B19 infection during pregnancy and in whom the time of acquisition was known was completed in Japan [243]. Nonimmune hydrops occurred in three fetuses whose mothers acquired B19 infection in the first half of pregnancy. Spontaneous abortion without hydrops and intrauterine growth restriction occurred in two fetuses whose mothers also developed B19 infection during the first half of pregnancy. The remaining eight fetuses, whose mothers acquired infection in the first and second half of pregnancy, were asymptomatic, although B19 DNA was detected in the immune serum of all of the infants. These results suggest that B19 transmission to the fetus is frequent, and fetal death may occur in almost half of the fetuses of infected mothers.

*†Numbers in parentheses in this column refer to gestational age at time of diagnosis of hydrops fetalis.*
*NR, not reported.*

A Swedish study of 92 pregnancies with unexpected fetal death occurring after 22 weeks of gestation found B19 DNA in 13 (14%) of the 92 fetuses [244]. Only 2 of the 13 were hydropic. The Swedish study again suggests that B19 infection may infect the fetus in the third trimester and result in fetal death or hydrops. This observation was confirmed in a larger study also from Sweden, where 47 cases of fetal deaths occurring after 22 weeks of gestation were identified and compared with 53 normal pregnancies [245]. Seven of the 43 intrauterine fetal deaths were positive for parvovirus B19 DNA, whereas B19 DNA was not detected in any of the normal pregnancies.

Dichorionic twin pregnancies affected by maternal B19 infections have also been reported [246,247]. These reports indicate that one or both fetuses may be infected, and only one fetus may be symptomatic even if both are infected.

In two studies, the presence of IgM to B19 or B19 DNA or both in maternal sera of pregnant women with a history of unexplained recurrent abortions was significantly higher than in pregnant women without a history of recurrent abortion, suggesting that women who are prone to recurrent abortion may be more likely to abort after a B19 infection than others [248,249].

B19 is a likely cause of fetal death in the first, second, and third trimesters, and most infected infants are not hydropic. The estimates of fetal deaths attributable to B19 range from 0 to 27%, making it difficult to assess the precise increase in fetal mortality attributable to B19.

## ASYMPTOMATIC FETAL INFECTION

Although published prospective studies of parvovirus B19 infection in pregnancy have varied in their estimates of adverse fetal outcome and rates of vertical transmission, most women infected during pregnancy deliver normal-appearing infants at term. Among these infants, some have asymptomatic infection [250]. A prospective study that combined serologic with virologic markers of infection suggested that intrauterine transmission is very high [23]. In this study, 43 pregnant women with a confirmed B19 infection were followed to delivery. The infants were tested at birth and at intervals throughout the 1st year of life for IgM and IgG to B19 and by PCR for viral DNA in serum, urine, or saliva. No fetal losses or cases of fetal hydrops were observed in this study; however, the rate of intrauterine viral transmission was 51% [23].

## BIRTH DEFECTS

There is circumstantial evidence that intrauterine parvovirus B19 infection may occasionally cause birth defects. The first case was reported in 1987 [251]. An aborted fetus at 11 weeks' gestation was described with striking ocular abnormalities including microphthalmia; aphakia; and dysplastic changes of the cornea, sclera, and choroid of one eye, and retinal folds and degeneration of the lens in the other eye [252,253]. The mother had a history of a rash illness with arthropathy at 6 weeks that was serologically confirmed as B19 infection. There have been few additional reports of malformations or developmental abnormalities in aborted fetuses or live-born infants after intrauterine infection, and the few cases that have been described could not be unequivocally attributed to infection with B19 [254–261].

There are no other data suggesting that B19 is an important cause of birth defects in live-born infants. In an uncontrolled study of 243 infants younger than 4 months with birth defects, none had IgM antibodies to B19 detected [221]. In a controlled study of 57 infants with structural abnormalities or stigmata of congenital infection, specific B19 IgM was not detected in cord blood of any of the affected infants or of the matched normal newborn controls [19]. There are also no data suggesting that structural defects are common in newborns after maternal B19 infection. After a large community-wide outbreak of EI, there was no increase in congenital malformations compared with the pre-epidemic and post-epidemic periods [262]. In the British study of maternal infections during pregnancy, outcomes were available for 186 patients; anencephaly was reported in 1 of the 30 fatal cases, but was not attributed to B19 infection, and hypospadias was present in 2 of the 156 live-born infants [20]. No new anomalies or serious neurodevelopmental problems were detected in the 114 infants followed clinically for at least 1 year [262]. In another prospective, but uncontrolled study of 39 pregnancies with maternal B19 infection, hypospadias was reported in 1 of the 37 live-born infants, and no abnormalities were reported in the one fatal case for which tissues were available [234].

## OTHER FETAL MANIFESTATIONS

Meconium ileus and peritonitis has been associated with maternal parvovirus B19 infection in a few reports [144,259]. Three infants with congenital anemia after maternal infection and intrauterine hydrops have also been reported [16]. All three infants had abnormalities on bone marrow examination and B19 DNA detected in bone marrow by PCR. Hyperechogenic bowel, common in fetuses infected with cytomegalovirus, has also been observed in a fetus with intrauterine B19 infection [263].

## FETAL HYDROPS

Although parvovirus B19 infection in utero may cause nonimmune hydrops fetalis, it is one of many causes of this syndrome and probably accounts for only 10% to 15% of fetal hydrops [144]. Hydrops fetalis is rare, occurring in only 1 in 3000 births; in 50% of cases, the etiology is unknown. In a study of 50 cases, B19 DNA was detected by in situ hybridization in the tissues of 4 fetuses; most of the cases were due to chromosomal or cardiovascular abnormalities [264]. In another study, B19 DNA was shown in 4 of 42 cases of nonimmune hydrops fetalis [265].

B19 infection is frequently associated with nonimmune fetal hydrops during local epidemics of EI. In a hospital series from England, 10 cases of B19-associated hydrops, representing 8% of all cases of nonimmune hydrops and 27% of anatomically normal cases of nonimmune hydrops, occurred over 17 years [255]. In a consecutive series of 72 patients with nonimmune hydrops from Germany, 3 (4.2%) had B19 infection [266]. In a series of 673 fetal and neonatal autopsies conducted over 6 years

in Rhode Island, 32 (0.7%) cases of hydrops were identified, and 5 (16%) of these had histologic and laboratory evidence of B19 infection [267,268]. In the British study, 1 of the 156 live-born infants had been diagnosed with intrauterine hydrops and recovered after intrauterine transfusion; of the six fatal cases that were positive for B19 DNA, hydrops was present in one of three fatal cases with laboratory-confirmed intrauterine infection [20,255]. Postmortem examination may be unable to identify hydrops in fetal death occurring in early pregnancy. Published reports suggest that nonimmune hydrops is an uncommon manifestation of fetal infection with B19.

### FETAL OUTCOME IN RELATION TO MATERNAL MANIFESTATIONS

No data suggest that the clinical manifestation of parvovirus B19 infection in the mother influences the pregnancy outcome. There is evidence for an association between a B19-affected fetus and maternal hypertension. Pregnancy-induced hypertension, preeclampsia, and eclampsia have been reported in some women with B19-associated fetal hydrops, and there is a record of improvement with spontaneous resolution of hydrops in one case [18,255,266,270–272,314]. Hypertension of pregnancy may be caused by poor fetal-placental perfusion, and there is an increased risk in pregnancies complicated by hydrops. It is unknown if there is an increased frequency of hypertensive disorders in B19-infected women compared with uninfected women, or if more careful monitoring of B19-infected women to detect findings of preeclampsia would be useful in identifying women at increased risk of B19-associated fetal hydrops.

### LONG-TERM OUTCOMES

The long-term outcomes of live-born infants infected in utero with parvovirus B19 are discussed in “Prognosis.”

## PATHOGENESIS OF INFECTION IN THE FETUS

### FETAL IMMUNE RESPONSES TO PARVOVIRUS B19

In studies in which serologic and virologic markers of infection have been examined, fetal immune responses to parvovirus B19 are variable [23,148,273]. B19-specific IgM in cord blood is a recognized marker of fetal infection, but sensitivity can be increased by adding other markers, such as IgA, PCR positivity, and persistence of B19 IgG at 1 year of age [23,148,273]. Infants exposed to B19 earlier in gestation may be less likely to show a positive IgM response owing to immaturity of the fetal immune system; for infants exposed later in gestation, the IgM response may be delayed because of interference by passively acquired maternal antibodies. In one study, only two of nine infected infants whose exposure occurred in the first 14 weeks of pregnancy were positive for B19 IgM at delivery, whereas all four infected infants exposed in the last trimester had B19-specific IgM in cord blood [23]. Serum IgA, similar to IgM, does not cross the placenta, so for some other congenital viral infections (e.g., rubella and human immunodeficiency virus [HIV]), viral-specific IgA responses in cord blood have been used to provide evidence of intrauterine infection [274]. In the only study of B19 in which this response was examined, B19 IgA in cord blood was associated with maternal infection with B19, and for a few infants, this was the only marker of intrauterine infection [23].

The fetal immune response to B19 may be important for preventing B19-induced red blood cell aplasia in the fetus and is suggested by the observed decreased rates of fetal death after 20 weeks of gestation. Viral clearance by the fetus may be prolonged. IgM specific to B19 may be detected at 18 weeks of gestation [275]. Fetal serum collected at 21 weeks' gestational age neutralizes B19 virus in vitro [276].

### PATHOGENESIS OF PARVOVIRUS B19 HYDROPS

Nonimmune hydrops is the best-characterized complication of fetal parvovirus B19 infection. Several mechanisms have been proposed, and more than one may contribute to hydrops [255]. Severe fetal anemia and thrombocytopenia is present in most cases [277]. Hemoglobin levels less than 2 g/dL are detected by cordocentesis of hydropic fetuses [269,278,279]. Hypoxic injury to tissues may result in increased capillary permeability. Severe anemia may also increase cardiac output, as evidenced by increases in umbilical venous pressure, and subsequently result in high-output heart failure [280]. Alternatively, myocarditis may precipitate heart failure. Reduced fetal myocardial function as shown by echocardiography occurs in some cases of fetal hydrops [270]. Regardless of the etiology, congestive heart failure could cause an increase in capillary hydrostatic pressure. Decreased venous return caused by massive ascites or organomegaly may lead to further cardiac decompensation. Hepatic function may be compromised by the extreme levels of extramedullary hematopoiesis, and lysis of B19-infected erythrocytes in the liver may cause hemosiderin deposition, fibrosis, and esophageal varices [271,272]. Impaired production of albumin could lead to a decrease in colloid osmotic pressure with transfer of fluid to the extravascular compartment. Placental hydrops may compromise further oxygen delivery to the fetus.

Finally, there is considerable evidence that fetal tissues other than erythroid cells may be susceptible to B19 infection. Virus has been shown in fetal myocytes, including cardiac myocytes, along with inflammatory changes; fetal myocarditis associated with B19 infection is well documented [131,257,281]. Histologic studies show vascular damage and perivascular infiltrates in other fetal tissues; it is unknown if this is due to B19 infection in endothelial cells or a nonspecific effect related to hypoxic damage.

## PATHOLOGY IN THE FETUS

### ANATOMIC AND HISTOLOGIC FEATURES

The hallmarks of fetal infection with parvovirus B19 are edema, anemia, and myocarditis, and these are reflected in the pathologic findings at autopsy, but otherwise

portmortem reports of gross and histopathologic pathology reveal few features specific for intrauterine B19 infection.* At post mortem, B19-infected fetuses are often described as pale with subcutaneous edema. Rashes are almost always absent; however, a “blueberry muffin” rash caused by extramedullary hematopoiesis in the skin may occur [288].

Fetal anemia is common in fetal deaths caused by B19, but does not occur in all cases.* The histologic findings suggestive of B19 infection include erythroid hypoplasia or occasionally hyperplasia characteristic of recovery. Extramedullary hematopoiesis is common in many organs, especially the liver and spleen. Nucleated red blood cells with amphophilic intranuclear inclusions (Figs. 27–3 and 27–4) are highly suggestive of B19 infection. These nucleated red blood cells are often found in the lumens of vessels and at sites of extramedullary hematopoiesis [131]. When stained with hematoxylin and eosin, the nuclei have an irregular band of dark chromatin. The center of the nucleus is lighter with a smooth texture. The specificity of intranuclear inclusions for fetal B19 infection is unknown, but it is probably high when associated with anemia and hydrops. Viral DNA or inclusions may also be present in macrophages and myocytes [131,281,290]. PCR to detect B19 DNA is the best method to diagnose B19 infection in a postmortem fetus. In one study, 6 of 34 cases of idiopathic nonimmune hydrops contained B19 DNA in either fetal or placenta tissues compared with no positive PCR results among 23 cases of hydrops that were noninfectious [338]. Histologic examination of these cases found no nucleated red blood cells with intranuclear inclusions.

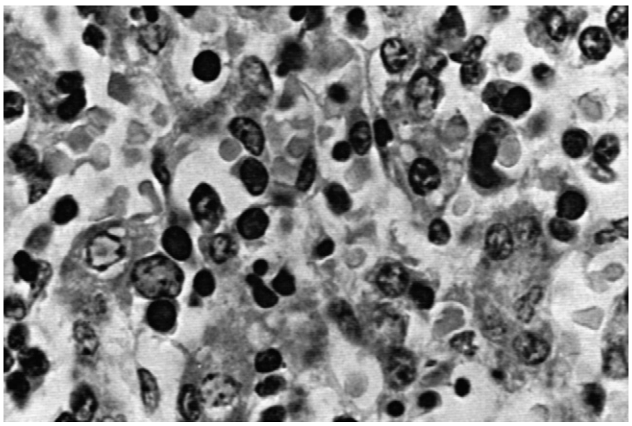

**FIGURE 27–4** Fetal liver from a case of parvovirus B19–associated nonimmune hydrops shows extramedullary hematopoiesis, intranuclear inclusions in erythroblasts, and focal areas with hemosiderin and fibrosis. (Hematoxylin & eosin stain.)

## PLACENTA

Parvovirus B19 infection of the placenta probably precedes fetal infection. The placenta is usually abnormal when associated with fetal death resulting from B19. Grossly, the placenta is often enlarged and edematous. Histologically, the placenta also contains nucleated red blood cells with typical intranuclear inclusions (see Fig. 27–4). Foci of red blood cell production also occur in the placenta, as does vascular inflammation [255,270,281]. In one study, vasculitis of villous capillaries or stem arteries occurred in 9 of 10 placentas [255]. There was swelling of endothelial cells, fragmentation of endothelial cell nuclei, and fibrin thrombi. B19 DNA occurs in endothelial cells of patients with myocarditis and in patients with cutaneous lesions, but has not been sought in placental endothelial cells.

The human placenta contains a B19 receptor, the neutral glycosphingolipid globoside, on the villous trophoblast layer of the placenta; the concentration of the globoside decreases with advancing pregnancy [291]. The highest concentration occurs in the first trimester with diminished reactivity in the second trimester. The presence of this globoside in the placenta provides a mechanism by which the virus infects the placenta and fetus. It also may explain why there is a difference in fetal outcome associated with gestational age. Maternal infections in late pregnancy have a better prognosis than infections occurring early in pregnancy. In addition to B19 receptors, there is also a B19-induced inflammatory response in the placenta, characterized by a significant number of $CD3^+$ T cells and the inflammatory cytokine interleukin-2 [292].

## HEART

The anemia associated with parvovirus B19 infection is due to a specific viral tropism for progenitor erythroid cells, specifically P antigen, which is found on these cells [293]. Clinical and laboratory evidence suggests, however, that B19 has a wider tropism than only erythroblasts [294]. Fetal myocardial cells contain P antigen [294]. Direct infection of myocardial cells after fetal B19 infection of extramedullary erythroid progenitor cells has been shown by in situ DNA hybridization or electron microscopy [60,72,131,295,296]. B19 myocarditis is also associated with acute lymphocytic infiltration. Case reports have described at least eight fetuses, five children, and four adults with myocarditis associated with a concurrent B19 infection [295,297–299,323–328]. B19 causes acute

and chronic myocarditis in infants. This myocarditis and the cardiac enlargement present in some B19-infected fetuses with hydrops suggest that B19 is pathogenic for the myocardium.* In infected fetuses, the heart may be normal or symmetrically enlarged suggesting congestive heart failure. Pericardial effusions are common. Myocytes with intranuclear inclusions occur infrequently. Mononuclear cell infiltrates occur occasionally, and B19 DNA, not associated with cells, can be found in the lumens of large vessels. As a response to injury, focal areas with dystrophic calcification or fibroelastosis have been reported.

One case-control study examined the relationship between congenital heart disease and B19 infection [301]. Five of 29 cases of congenital heart disease had B19 DNA detected in cardiac tissue using PCR compared with none of 30 matched case controls. This difference was significant ($P < .02$). Other infections, including herpes simplex virus, cytomegalovirus, rubella, and toxoplasmosis, were excluded. Additional studies testing for B19 infection of congenital heart disease are appropriate.

### OTHER ORGANS

Numerous other anatomic abnormalities have been described in association with parvovirus B19 infection of the fetus. The occurrence of these abnormalities is so infrequent, however, that it is unlikely that any are related to B19. These associated abnormalities include dystrophic calcification of the brain and adrenal glands, anencephaly and ventriculomegaly, pulmonary hypoplasia, hypospadias, cleft lip, meconium peritonitis, corneal opacification and angioedema, and thymic abnormalities.*

## DIAGNOSTIC EVALUATION AND MANAGEMENT OF THE WOMAN AND FETUS EXPOSED TO OR INFECTED BY PARVOVIRUS B19 DURING PREGNANCY

### OVERVIEW

Management of a pregnant woman exposed to parvovirus B19 requires knowledge of the prevailing status of EI in the community, a detailed history of the exposure, knowledge of characteristic symptoms and signs of maternal EI and B19 infection in the fetus, appropriate laboratory tests needed to confirm maternal and fetal infection, knowledge of the methods for monitoring the fetus at risk for nonimmune hydrops, knowledge of therapeutic approaches for treating the hydropic fetus, and information about the prognosis of maternal and fetal infection and the expected outcomes for the therapeutic intervention.

### PREVALENCE OF ERYTHEMA INFECTIOSUM

The community health or school health departments may know if EI is endemic or epidemic in the community, increasing the probability of primary infection in susceptible pregnant women.

*References [131,255,257,258,267,275,281,297,300].

*References [18,20,131,254–256,258–261,273,286,302,303].

### HISTORY OF EXPOSURE

Pregnant women who are potentially exposed to a person with EI should be asked about the type of exposure, including duration and location, brief or prolonged, household or workplace, indoor or outdoor, and contact with respiratory secretions. Exposure to a child within the household constitutes the highest risk.

Did the contact have symptoms typical of EI, including a low-grade fever and a typical slapped-cheek rash that soon spread to the trunk or limbs in a lacy pattern? Did the rash disappear and then reappear when the child was warm from exercise or bathing? Had the child been exposed to any known source of EI, such as an outbreak in school, preschool, or day care center; a family gathering; a play group; or church nursery? Was the child evaluated by a physician familiar with viral exanthems?

### CLINICAL FEATURES SUGGESTING SIGNS AND SYMPTOMS OF PARVOVIRUS B19 INFECTION IN THE PREGNANT WOMAN

It should be determined if the mother's signs and symptoms are compatible with parvovirus B19 infection in adults, including at least one or more of the following: malaise, arthralgia, rash, coryza, or fever ($\geq$38° C). Pregnant women with such symptoms, especially malaise with symmetric arthralgias in the hands, wrists, knees, or feet, should be considered at high risk and tested for a recent B19 infection. In Barcelona, Gratacos and coworkers [22] found that only 30% of 60 IgM-positive women recalled any such symptoms. Pregnant women without such systemic symptoms but with a rapidly enlarging uterus (fundal height exceeding dates by >3 cm), an elevated serum alpha fetoprotein, preterm labor, or decreased fetal movement should be asked about B19 exposure. If ultrasonography reveals evidence of hydrops fetalis, or the fetus has ascites, pleural or pericardial effusion, skin thickening, polyhydramnios, or placentomegaly, maternal B19 testing is appropriate.

### LABORATORY DIAGNOSIS IN THE PREGNANT WOMAN

With evidence of maternal parvovirus B19 exposure or maternal disease, maternal serum should be tested for IgG and IgM antibodies to B19. If there is probable or possible exposure, the first serum should be drawn at least 10 days after the exposure. Fetal morbidity is unlikely to occur within 2 weeks of exposure, so immediate serologic testing is appropriate for a woman or fetus with symptoms or signs of B19 infection.

If an initial serum sample is IgG-positive but IgM-negative, this indicates a previous maternal infection, and additional testing is usually unnecessary. The IgM assay is sensitive with few false-negative reactions. If an initial serum sample is negative for IgM and IgG, this indicates no previous maternal infection, and B19 is not responsible for maternal symptoms and signs or for hydrops fetalis.

If the IgM result is positive, a recent B19 infection is established regardless of the IgG titer. A concomitant

negative IgG titer indicates an early B19 infection without time for IgG to be detectable. If PCR is available, detection of maternal and fetal viremia by PCR for B19 DNA is also diagnostic of B19 infection. Viremia may precede the development of IgM antibodies by 7 to 14 days and may persist for several months after a primary infection.

A useful adjunct to IgM testing is measurement of IgG avidity to the VP1 capsid protein [304,305]. After a primary infection, initial IgG antibodies have low avidity for binding to the VP1 capsid. This avidity increases slowly over several weeks or months, and avidity can be used as a confirmatory test for the occasional patient for whom the diagnosis is initially unclear.

With a positive maternal IgM, the fetus must be examined for signs of hydrops fetalis by ultrasonography within 24 to 48 hours. If the gestational age is less than 18 weeks, the absence of hydrops may not be reassuring because hydrops could appear later. Several cases of severe hydrops fetalis spontaneously reverting to normal over 3 to 6 weeks have been reported, so advice about pregnancy termination is difficult [270,273,306].

Detection of maternal and fetal levels of B19 DNA (viral load) is a highly sensitive test for identifying B19 infection [305,307–309]. Peak maternal viral loads occur about 1 week after maternal infection, and fetal viral loads, approximately equal to maternal levels, occur 1 to 3 weeks after maternal infection. The prolonged persistence of B19 DNA in the blood means additional testing is required to establish the time of maternal infection. Viral loads are not predictive of the severity of fetal infection.

## FETAL MONITORING

For a fetal gestational age of greater than 20 weeks, an initial negative ultrasound scan should be repeated weekly to detect hydrops. The number of weekly ultrasound scans that should be performed is controversial: Rodis and colleagues [256] originally suggested continuing weekly scans for 6 to 8 weeks after exposure; they reported a fetal death at 23 weeks of gestation, however, after maternal fever and arthralgias in the first trimester The interval between maternal B19 infection and fetal morbidity is uncertain. Based on this report, other authors recommended weekly ultrasound scans for 14 weeks after maternal B19 infection [306]. This monitoring often appeals to pregnant women fearful of fetal death, but it is time-consuming and expensive.

The duration of monitoring for hydrops fetalis might be best determined by examination of the interval between maternal exposure or symptoms of B19 infection and the appearance of hydrops fetalis or fetal death. Table 27–2 summarizes reports with adequate information to evaluate the interval, which include 14 intervals between maternal B19 exposure or infection and fetal death and 7 intervals between maternal exposure or infection and the first diagnosis of hydrops fetalis. The intervals range from 1 to 19 weeks (median 6 weeks). Between 3 and 11 weeks, 17 of 21 (81%) cases of hydrops fetalis developed. Because 11 of the 21 cases developed 4 to 8 weeks after maternal exposure or infection, this is the most common interval between infection and the detection of fetal hydrops.

Based on these observations, weekly ultrasound monitoring of the fetus for 12 weeks after maternal exposure is optimal, but does not detect all delayed cases and may be expensive. Such frequent scanning may not be considered cost-effective because the incidence of hydrops after maternal B19 infection is low in many studies. In our study, none of the 52 fetuses born to pregnant women positive for B19 IgM developed hydrops fetalis; however, the 95% confidence interval based on our sample size ranged from 0 to 8.6% risk for hydrops fetalis [227]. Using maternal symptoms as criteria for maternal B19 infection, other studies have suggested a 9% incidence of fetal death owing to B19 in women positive for B19 IgM [20].

The fetus in a B19-infected woman may be monitored with serial maternal serum alpha fetoprotein (MSAFP) measurements [310]. One report found elevated MSAFP in five B19 IgM–positive pregnancies associated with fetal death, but no fetal deaths in 11 IgM-positive women with B19 infection but normal MSAFP values [278]. A case of B19-associated fetal death discovered because of elevated MSAFP at 16 weeks in a routine test in an asymptomatic woman has also been described [18]. In adding a seventh case of fetal death associated with elevated MSAFP in women positive for B19 IgM, Bernstein and Capeless [310] suggested using MSAFP values to indicate a good fetal prognosis.

A German study found, however, that neither MSAFP nor human gonadotropin was a marker of B19-infected pregnancies, although both were frequently elevated when complications occurred [311]. The study included 35 pregnant women with fetal complications associated with B19; significant elevations of MSAFP occurred in 13 of 35 women, and elevations of human gonadotropin occurred in 25 of 35 women. The investigators tested 137 serum samples from 65 pregnant women without acute B19 infection and no fetal complications. Of the 30 women without fetal complications, there were significant elevations of MSAFP in only 2 women, and elevations of human gonadotropin occurred in only 5 women. Neither MSAFP nor human gonadotropin was a marker for a poor pregnancy outcome early on, but these proteins were frequently elevated when complications developed. Despite this study, there is insufficient experience using MSAFP, and MSAFP measurements at any gestational age are relatively nonspecific indicators of fetal well-being.

Electronic fetal monitoring is ineffective in detecting hydrops fetalis and predicting the outcome of pregnancy in women positive for B19 IgM. Contraction stress tests and nonstress tests are not accurate predictors of fetal well-being in cases of fetal anemia and hydrops fetalis. Similarly, fetal assessment with estriol measurements or other biochemical markers have no documented role in cases of hydrops fetalis.

Because fetal ultrasonography is readily available and provides rapid specific information about hydrops fetalis, it is the best method to monitor the fetus after maternal B19 infection. Doppler ultrasound of the middle cerebral artery may also be used to reveal increased peak systolic velocity suggestive of fetal anemia [312].

## FETAL THERAPY

If hydrops fetalis is detected before 18 weeks, there is no effective intervention. Other causes of hydrops, such as chromosomal disorders or anatomic abnormalities, should be assessed. If the fetus is still viable via ultrasound at 18 weeks of gestation, percutaneous umbilical blood sampling, or cordocentesis, can be considered. At 18 weeks, the umbilical vein diameter is about 4 mm, the minimum size required for successful percutaneous umbilical blood sampling. Fetal blood should be obtained for hematocrit, reticulocyte count, platelet count, leukocyte count, anti-B19 IgM, karyotype, and tests for B19 DNA by PCR. The hematocrit must be determined immediately, and if fetal anemia is present, an intrauterine intravascular fetal transfusion is performed with the same needle puncture.

If the fetus is between 18 and 32 weeks of gestation when hydrops fetalis is detected, fetal transfusion should be considered. There are many successful reported cases of fetal transfusion for B19-induced hydrops fetalis, and some have long-term follow-up data, but the success rate of the procedure remains unknown [300,313–318]. Two or three separate transfusions are usually required before resolution of the fetal anemia and hydrops fetalis, increasing the 1% to 2% risk of each single percutaneous umbilical blood sampling procedure. Resolution of the hydrops usually occurs 3 to 6 weeks after the first transfusion. Although spontaneous resolution has been reported, it seems appropriate not to risk an uncertain outcome because the longer the fetal transfusion is delayed, the less likely it is to be successful, and the worse the potential harm to the fetus caused by continued fetal hypoxia.* Thrombocytopenia is also common and, if severe, may require intrauterine platelet transfusion [277]. There is also one report of a hydropic infant successfully treated with intraperitoneal γ-globulin high in titer to B19 [319]. For fetuses at 32 weeks' gestation or greater when hydrops is discovered, immediate delivery with neonatal exchange transfusion, thoracentesis, and paracentesis as indicated is usually the safest management.

## DIFFERENTIAL DIAGNOSIS

Recalling that the hallmarks of fetal infection with parvovirus B19 are anemia, hydrops, and myocarditis helps in compiling a differential diagnosis. For infants with anemia, the differential diagnosis includes all the known causes of fetal anemia, such as fetal-maternal transfusion, intracranial bleeding, blood group incompatibilities, congenital anemias such as Diamond-Blackfan syndrome, nutritional deficiencies, and inborn metabolic errors. Fetal hydrops and fetal and placental edema may be associated with other congenital infections, particularly congenital syphilis, chromosomal abnormalities, immune hydrops associated with blood group incompatibilities, hypothyroidism, and heart and renal failure.

## PROGNOSIS

Pregnant women can be reassured about the relatively low risk of fetal morbidity resulting from exposure to parvovirus B19. About half of women are already seropositive, and the seronegative maternal B19 infection rate ranges from about 29% for exposures by the woman's own children to 10% to 18% for other exposures. The expected fetal morbidity and mortality risk is around 2% (1 in 50). The overall risk of fetal death ranges from 0.3% ($\frac{1}{2} \times \frac{3}{10} \times \frac{1}{50} = \frac{3}{1000}$) to 0.1% ($\frac{1}{2} \times \frac{1}{10} \times \frac{1}{50} = \frac{1}{1000}$) [227]. Live-born infants infected in utero may die shortly after birth. There is one report of two infants born prematurely at 24 weeks and 35 weeks of age who developed an illness characteristic of congenital viral infection, including placentomegaly, petechial rash, edema, hepatomegaly, anemia, thrombocytopenia, and respiratory insufficiency; both died postnatally [320]. Both infants had nuclear inclusions in erythroid precursor cells, and PCR confirmed the presence of B19 DNA in one of the infants.

There is one report describing three live-born infants with severe CNS abnormalities after serologically confirmed maternal B19 infection [302,321]. Subsequent case reports have also identified CNS manifestations including mild to moderate hydrocephalus with CNS scarring associated with fetal B19 infection [322]. These reports suggest possible long-term neurologic sequelae in surviving infants that may not be apparent at birth.

Data regarding the long-term outcomes of live-born children infected in utero or born of mothers infected during pregnancy are very limited. In one study, 113 pregnant women with B19 infection during pregnancy and a control group of immune women were questioned about the health and development of their children when the median age of the children was 4 years for both groups [262]. The incidence of development delays in speech, language, information processing, and attention was similar between the study group and the controls (7.3% versus 7.5%). Two cases of cerebral palsy were found in the study group compared with none in the controls. Although not statistically significant, this 2% incidence of cerebral palsy in the infected group is 10-fold higher than the reported national incidence [262].

In a British study of 427 pregnant women with B19 infection and 367 of their surviving infants, 129 surviving infants were followed up at 7 to 10 years of age [329]. The follow-up included questionnaires to obstetricians and general practitioners on outcome of pregnancy and health of surviving infants. Maternal infection was confirmed by B19-specific IgM assay or IgG seroconversion or both. An excess rate of fetal loss was confined to the first 20 weeks of gestation and averaged 9%. There were seven cases of fetal hydrops with maternal infections between 9 and 20 weeks of gestation. There were no abnormalities attributable to B19 infection found at birth in surviving infants. There were no late effects observed between 7 and 10 years of age. The conclusions of this study were as follows: (1) Approximately 1 in 10 women infected before 20 weeks of gestation have a fetal loss owing to B19; (2) the risk of an adverse outcome of pregnancy beyond this stage is unlikely; and (3) infected women

can be reassured that the risk of congenital abnormality owing to B19 is less than 1%, and long-term development will be normal.

One study used IQ testing and standard neurodevelopmental tests to assess 20 children who had B19-induced fetal hydrops and intrauterine transfusion of packed red blood cells [313]. IQ testing of the 20 children between 13 months and 9 years of age revealed that all of the children ranged within 2 standard deviations of a population norm. There was no significant developmental delay. This study concluded that children who survived successful intrauterine transfusion from B19 anemia and hydrops had a good neurodevelopmental prognosis.

Another, more recent, study came to an opposite conclusion [330]. That study used Bayley scales of infant development to assess 16 transfused B19 hydropic fetuses who were live-born and survived. Assessments were done between 6 months and 8 years of age. Postnatal growth and health status were reported to be normal. Mild to severe developmental delay was observed in five of the children, suggesting that B19 infection may induce brain damage [330]. Most infants infected in utero with B19 survive and develop normally, but it is unlikely that all infected infants, whether owing to direct viral infection of the brain or as a consequence of intrauterine hypoxia, will develop normally.

# PREVENTION

## GENERAL MEASURES

Because parvovirus B19 is usually endemic in most communities, what is the appropriate management for pregnant women with daily contact with children? The prevalence of seropositivity (immunity) to B19 among pregnant women varies according to geographic location, sex, age, and race. Assuming that on average 50% of pregnant women are immune, that during endemic periods between 1% and 4% of susceptible women become infected during pregnancy, and that the rate of fetal death after maternal infection is 2%, the occupational risk of fetal death for a pregnant woman with unknown serologic status would be between 1 in 1000 and 1 in 2500. These rates are so low that they would not justify intervention such as serologic testing for pregnant women or furloughing or temporarily transferring pregnant seronegative employees to administrative or other positions without child contact. A detailed cost-benefit analysis for Germany reached the same conclusion [331]. During epidemic periods in specific schools, when the infection rates may be 5-fold to 20-fold higher, serologic testing or temporary transfer of pregnant employees may occasionally be appropriate, and some anxious women may choose to leave the workplace.

Given the low risk for individual pregnant women, seronegative women should not send their own children away. Schools and day care centers cannot stop B19 outbreaks by excluding children with rash illnesses because B19 is transmissible before the rash appears. Whether B19 can be transmitted via breast-feeding is unknown.

## VACCINE DEVELOPMENT

For most women, fetal B19 infections during pregnancy do not occur from occupational exposure, but rather from exposure to school-age children at home. Given this factor, the highly communicable and endemic nature of the infection, the broad spectrum of illness that B19 causes, and the large portion of the population (30% to 50%) who are susceptible, an effective B19 vaccine, preferably administered in infancy, is appropriate, and at least one vaccine is being developed [332]. This vaccine comprises the major B19 capsid proteins VP1 and VP2 and is administered with a squalene adjuvant, MF59. After testing in a limited number of subjects, this vaccine seems safe and induces neutralizing antibodies. Studies using volunteers challenged with wild-type B19 should be able to assess efficacy. A vaccine that induces sustained neutralizing antibody IgG levels to B19 should be effective given that prior immunity to natural B19 infection protects against reinfection.

CHAPTER

28

# RUBELLA

Stanley A. Plotkin ✪ Susan E. Reef ✪ Louis Z. Cooper ✪ Charles A. Alford, Jr.

## CHAPTER OUTLINE

The impact of rubella virus infection and the progress made toward controlling congenital rubella infection have been well chronicled [1–9]. Rubella was first recognized in the mid-18th century as a clinical entity by German researchers, who called it *Rötheln*. They considered it to be a modified form of measles or scarlet fever [1]. Manton [10] first described it as a separate disease in the English literature in 1815. In 1866, Veale [11] gave it a "short and euphonious" name—*rubella*. The disease was considered mild and self-limited.

Rubella became a focus of major interest in 1941, after Gregg [12], an Australian ophthalmologist, associated intrauterine acquisition of infection with production of cataracts and heart disease. Although his findings were initially doubted, numerous reports of infants with congenital defects after maternal rubella infection soon appeared in the literature [1]. Subsequent investigations showed that the major defects associated with congenital rubella infection included congenital heart disease, cataracts, and deafness. Mental retardation and many defects involving almost every organ have also been reported [2–4,7,13,14]. Before the availability of specific viral diagnostic studies, the frequency of fetal damage after maternal infection in the first trimester was estimated to be greater than 20%, a figure now known to be much too low.

Recognition of the teratogenic potential of rubella infection led to increased efforts to isolate the etiologic agent. The viral cause of rubella was suggested by experimental infections in humans and monkeys in 1938, but was not confirmed until the isolation of the viral agent in cell cultures was reported independently in 1962 by Weller and Neva at Harvard University School of Public Health and by Parkman, Buescher, and Artenstein at Walter Reed Army Institute for Research [15–20]. This accomplishment paved the way for the development of serologic tests and a vaccine [2–4,21–23]. Efforts to develop a vaccine were hastened by events associated with a worldwide rubella pandemic in 1962–1964, which in the United States resulted in approximately 12.5 million cases of clinically acquired rubella, 11,000 fetal deaths, and 20,000 infants born with defects collectively referred to as congenital rubella syndrome (CRS); 2100 infants with CRS died in the neonatal period [24]. The estimated cost to the U.S. economy was approximately $2 billion. Routine use of rubella vaccine, in a two-dose schedule as measles-mumps-rubella vaccine (MMR), has not prevented importation-related infection, but it has eliminated endemic rubella in the United States [25]. CRS remains a problem in many countries, however, with current estimates of 110,000 new cases annually in developing countries [26].

In 1969, three strains of live-attenuated rubella vaccine were licensed in various countries: HPV-77 (high-passage virus, 77 times), grown in duck embryo for five passages (DE-5) or dog kidney for 12 passages (DK-12); Cendehill, grown in primary rabbit cells; and RA 27/3 (rubella abortus, 27th specimen, third explant), grown in human diploid fibroblast culture [27–29]. The RA 27/3 vaccine has been used exclusively in the United States since 1979 and is

DOI: 10.1016/B978-1-4160-6400-8.00028-6

now the only strain in global use outside of Japan and China [2–4,7,30,31].

In addition to providing the impetus for vaccine research and development, the rubella pandemic provided the scientific community with a unique opportunity to gain knowledge about the nature of intrauterine and extrauterine infections and the immunity stimulated by both. The quest for more knowledge using the tools of molecular biology has continued since vaccine licensure and serves as a tribute to Gregg's historic contribution to our understanding of intrauterine infection.

Much interest has focused on the epidemiology of rubella and CRS in countries with immunization programs, the desirability of introducing vaccine in countries without a program, and the optimal strategy to control congenital rubella (i.e., universal immunization versus selective immunization of females versus combined strategy of universal vaccination and selective immunization) [3,5–7,32–38]. Vaccination of all children and of susceptible adolescents and young adults, particularly women, has had such a dramatic impact on the occurrence of rubella and congenital rubella in the United States that it has resulted in the elimination of endemic rubella and CRS from the United States [5,24,33,39,40]. Given the magnitude of international travel, the goal of eradication of rubella will remain elusive until similar goals are adopted by other countries. In 2003, the Pan American Health Organization (PAHO) adopted a resolution calling on all countries of the Western Hemisphere to eliminate rubella by 2010, a goal that appears to have now been achieved [41]. Among developing countries, rubella immunization has not yet been given priority, however.

Duration and quality of vaccine-induced immunity [5,8,42–61] and adverse events associated with immunization, particularly arthritis and the risk of the vaccine to the fetus [5,8,62–69], have been a concern, but the vaccine continues to confer long-lasting immunity, while placing the vaccinated person at minimal risk of adverse events. Success in eliminating endemic disease in the United States and the absence of teratogenicity observed after massive immunization programs (2001–2002) in Latin America offer considerable assurance about the long-term efficacy and safety of rubella vaccine. In Brazil, 28 million women were immunized in mass campaigns, and in Costa Rica, more than 2400 susceptible pregnant women were immunized. Although infants were infected, none had evidence of CRS.

Research on the characteristics of the rubella virus, its effect on the developing fetus, the host's immune response, and diagnostic methodology has yielded new information about the structural proteins of the virus and about the difference in the immune response to these proteins after congenital and acquired infections [70–90]. Differences in antibody profile may be useful in diagnosing congenital infection retrospectively and may provide further information on the pathogenesis of congenital infection [68,89,91]. Techniques that detect rubella-specific antibodies within minutes have been developed by using latex agglutination and passive hemagglutination [92–98]. Studies to examine the subclass distribution of IgG and the kinetics of rubella-specific immunoglobulins (including IgA, IgD, and IgE) after acquired rubella, congenital infection, and vaccination may eventually lead to the development of additional diagnostic tools [99–103]. In particular, rubella IgG avidity testing can be helpful in distinguishing between recently acquired and remote infection [104–106].

Improved laboratory methods defined the risk of fetal infection and congenital damage in all stages of pregnancy [107–114]. The risk of fetal infection after first-trimester maternal infection and subsequent congenital anomalies after fetal infection may be higher than previously reported (81% and 85% in one study) [109]. The fetus may be at risk of infection throughout pregnancy, even near term, although the occurrence of defects after infection beyond 16 to 18 weeks of gestation is small. Sensitive laboratory assays have shown that subclinical reinfection after previous natural infection, as after vaccination, may be accompanied by an IgM response, making differentiation between subclinical reinfection and asymptomatic primary infection difficult sometimes [45,55,57,59]. IgG avidity testing may be helpful in this situation. Although reinfection usually poses no threat to the fetus, rare instances of congenital infection after maternal reinfection have been reported.*

Follow-up of patients with congenital rubella has provided information about the pathogenesis, immune status, interplay between congenital infection and human leukocyte antigen (HLA) haplotypes, and long-term outcome associated with congenital infection [121–138]. These studies have documented that congenital infection is persistent; that virtually every organ may be affected; and that autoimmunity and immune complex formation are probably involved in many of the disease processes, particularly in the delayed and persistent clinical manifestations. They also confirm earlier studies, noting an increased risk of diabetes mellitus and other endocrinopathies in patients with CRS compared with rates for the general population.

# VIRUS

## MORPHOLOGY AND PHYSICAL AND CHEMICAL COMPOSITION

Rubella virus is a generally spherical particle, 50 to 70 nm in diameter, with a dense central nucleoid measuring 30 nm in diameter. The central nucleoid is surrounded by a 10-nm-thick, single-layered envelope acquired during budding of the virus into cytoplasmic vesicles or through the plasma membrane [139–153]. Surface projections or spikes with knobbed ends that are 5 to 6 nm long have been reported. The specific gravity of the complete viral particle is $1.184 \pm 0.004$ g/mL, corresponding to a sedimentation constant of $360 \pm 50$ Svedberg units [139].

The wild-type virus contains within its core infectious positive strand RNA (molecular weight of 3 to $4 \times 10^6$)

*References 45, 47, 49, 51, 55–57, 59, 115–120.

containing 9800 nucleotides [124]. Full-length and subgenomic RNA are produced, and it is from the latter that viral structural proteins are translated. The rubella virus envelope contains lipids that differ quantitatively from lipids of the plasma membrane and are essential for infectivity [154,155]. Rubella virus is heat labile and has a half-life of 1 hour at 57° C [156]. In the presence of protein (e.g., 2% serum albumin), infectivity is maintained for 1 week or more at 4° C, however, and indefinitely at −60° C. Storage at freezer temperatures of −10° C to −20° C should be avoided because infectivity is rapidly lost [156,157]. Rubella virus can also be stabilized against heat inactivation by the addition of magnesium sulfate to virus suspensions [158]. Specimens for virologic examination should be transported to distant laboratories packed in ice rather than frozen, with the addition of stabilizer if possible. Infectivity is rapidly lost at pH levels less than 6.8 or greater than 8.1 and exhausted in the presence of ultraviolet light; lipid-active solvents; or other chemicals such as formalin, ethylene oxide, and β-propiolactone [156,159–161]. Infectivity of rubella in cell culture is inhibited by amantadine, but this drug seems to have no therapeutic effect [162–165].

Several laboratories have described the structural proteins of rubella virus and determined the nucleotide sequence of the genes coding for these proteins [70,85,139,166–169]. Originally, three structural proteins were identified and designated as VP-1, VP-2, and VP-3 [166]. These three major structural proteins now are designated E1, E2, and C, with relative molecular weights of 58,000, 42,000 to 47,000, and 33,000 [71–73]. E1 and E2 are envelope glycoproteins and make up the characteristic spikelike projections that are located on the viral membrane. Structural protein C, which is not glycosylated, is associated with the infectious 40S genomic RNA to form the nucleocapsid [75]. The E2 glycopeptide has been shown on polyacrylamide gels to be heterogeneous with two bands, which are designated E2a (relative molecular weight of 42,000) and E2b (relative molecular weight of 47,000) [71].

Monoclonal antibody studies have begun to delineate the functional activities of these structural proteins. E1 seems to be the viral hemagglutinin and binds hemagglutination-inhibiting and hemolysis-inhibiting antibody; E2 does not seem to be involved in hemagglutination [70,72,74,76–79]. Monoclonal antibodies specific for E1 and E2 have neutralizing activity because both proteins are involved in cell entry.*

Studies also indicate that there are multiple epitopes on the structural proteins that are involved in hemagglutination inhibition (HI) and neutralizing activities [79,82]. Molecular analyses of rubella viruses isolated during 1961–1997 from specimens obtained in North America, Europe, and Asia have documented the remarkable antigenic stability of the E1 envelope glycoprotein [84]. E1 amino acid sequences have differed by no more than 3%, indicating no major antigenic variation over the 36-year period that spanned the major worldwide pandemic of 1962–1964 and the 30 years since introduction of rubella vaccine. Two clades and 10 genotypes were evident, however [172]: Genotype I was isolated before 1970 and grouped into a single diffuse clade, indicating intercontinental circulation, whereas most of the post-1975 viruses segregated into geographic clades from each continent, indicating evolution in response to vaccination programs. Clade 2 seems to be Asian in origin [173].

Figure 28–1 shows the geographic distribution of the genotypes [174]. The availability of molecular analysis and the minor variations in amino acid sequences have provided an additional tool for monitoring the sources of infection in areas where indigenous rubella has been greatly reduced by high levels of immunization. As discussed in more detail later, the complexity of the

*References 74, 80, 89, 90, 170, 171.

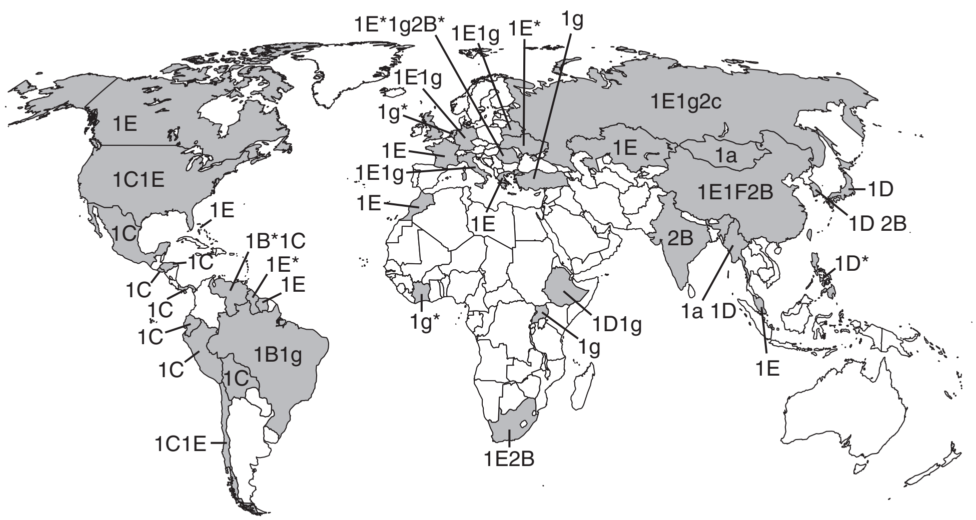

**FIGURE 28–1 Global distribution of indigenous rubella viruses, 1995-2006.** Data summarize information available as of the end of November 2006. *Shading* indicates countries where circulating rubella viruses have been identified. During this period, some countries reduced indigenous rubella transmission to low levels (e.g., Canada, the United Kingdom, and the United States).

*Viruses characterized after being imported into another country.

antigenic nature of the rubella virion affects the ability of the host to respond to the full complement of antigens and affects the various antibody assays required to detect all the corresponding antibody responses (see "Natural History").

## CLASSIFICATION

Rubella has been classified as a member of the Togaviridae family (from the Latin word *toga*, meaning "cloak"), genus *Rubivirus* [175,176]. No serologic relationship exists between rubella and other known viruses. Minor biologic differences identified in different passaged strains of rubella virus are not reflected in the antigenic differences assessed by comparing protein composition or serologic reactions [139,169,177,178]. Differences in the immune response after immunization with the various vaccines now in use are not caused by inherent differences in the viral strain, but rather by modification of the viruses during their attenuation in cell culture [30]. The reported variation in the virulence of rubella epidemics does not seem to be explained by the molecular analyses described earlier, but it may result from differences in population susceptibility and underreporting of cases of congenital rubella [179–186].

## ANTIGEN AND SEROLOGIC TESTING

Rubella virus may be isolated in cell culture from nasopharynx, serum, urine, cataracts, placenta, amniotic fluid, and fetal tissues. The nasopharynx is the best source because excretion is more persistent there. RK13 and Vero cells are the best substrates. Virus isolation takes many days to become positive and confirmed by neutralization, however. During pregnancy, it is important to attempt more rapid diagnosis through the use of reverse transcriptase polymerase chain reaction (PCR) [187]. Amniotic fluid is the best source, although chorionic villi and placenta may be positive. Primers come from nucleotides located between 731 and 854 of the E1 gene [188,189].

Purified rubella virus has many antigenic components associated with the viral envelope and the ribonucleoprotein core [161,167]. These antigens and the ability of specific antiserum to neutralize virus form the basis for the wide variety of serologic methods available to measure humoral immunity after natural and vaccine-induced infection.

The ability of antibodies against E1 and E2 proteins to inhibit agglutination of erythrocytes by the surface hemagglutinin (HA antigen) forms the basis for the HI test, which previously was the most popular rubella serologic test. The HA antigen was originally prepared from BHK tissue culture fluids and then from alkaline extracts of infected BHK-21 cells [23,190]. This antigen can agglutinate various red blood cells, including newborn chick, adult goose, pigeon, and human group O erythrocytes [191]. Rubella hemagglutinin is unique in its dependency on calcium ions to attach to red blood cell receptors [191,192]. After extraction from infected cells, rubella hemagglutinin is stable for months at −20° C, several weeks at 4° C, and overnight at 37° C, but is destroyed within minutes after heating to 56° C [190,192]. The HA antigen can be protected from ether inactivation by pretreatment with polysorbate 80 (Tween 80).

Cells and serum contain heat-stable β-lipoproteins that can inhibit rubella hemagglutination and give rise to false-positive results [23,161]. Although it has been reported that nonspecific inhibitors do not interfere in the HI test if the HA antigen and erythrocytes are mixed before addition of serum, the recommended method is to pretreat the sera to remove these inhibitors [161,193]. Earlier test procedures used kaolin adsorption for removal of these nonspecific inhibitors; however, many faster and more specific methods are now used, such as treatment with heparin-$MnCl_2$ or dextran sulfate-CaCl [194,195].

Cell-associated complement fixation antigen was first derived from infected rabbit kidney (RK-13) and African green monkey kidney cell cultures and later prepared from alkaline extracts of infected BHK-21 cells [22,196]. There are two complement fixation antigens: One is similar in size and weight to the hemagglutinin and infectious virus, and the other is smaller and "soluble" [170,197,198]. The antibody response as measured by the soluble antigen develops more slowly than the response to the larger antigen, which parallels the HI response. In contrast to the HA antigen, complement fixation antigens do not lose their antigenicity after either treatment [196,198].

Various precipitin antigens have been shown serologically; two of these, the theta and iota antigens, are associated with the viral envelope and core [199–201]. The antibody response to these two antigens is of interest. Antibodies to the theta antigen rise promptly and persist. Antibodies to the iota antigen are detectable later and for a shorter time [202]. The RA 27/3 vaccine seems to be unique among vaccine strains in its ability to elicit a response to the iota antigen, making its immune response more similar to natural infection. The significance of this observation is unclear [203].

Rubella virus antigen-antibody complexes (involving the envelope and the core antigens) cause aggregation of platelets [204,205]. The main platelet aggregation activity seems to reside with the viral envelope, however.

Antibody directed against the rubella virus can also be measured by virus neutralization in tissue culture [2–4,21, 206–208]. Although the presence of neutralizing antibodies correlates best with protective immunity, neutralization assays are time-consuming, expensive, and relatively difficult to perform. Laboratories have traditionally performed the complement fixation and HI tests. Because the complement fixation test is insensitive for screening purposes and cannot detect an early rise in antibody in acute acquired infection, the HI test has been the most widely used assay.*

Numerous more rapid, easily performed, reliable, and sensitive tests have replaced the HI test for routine use [92,210,211], including passive (or indirect) hemagglutination; single radial hemolysis (also known as hemolysis in gel), which is used widely abroad; radioimmunoassay; immunofluorescence; and enzyme immunoassay tests, also referred to as enzyme-linked immunosorbent assays [206,209–240]. Rapid latex agglutination and passive hemagglutination assays can provide results in minutes for

*References 2–4, 161, 202, 206, 209, 210.

screening and diagnostic purposes [92–98]. The numerous assays now available and their greater sensitivity compared with the HI test have led to some confusion about the level of antibody that should be considered indicative of immunity (see “Update on Vaccine Characteristics”) [48,58,61,210,238]. The HI test remains the reference test against which other assays are compared, however.

Immunoglobulin class-specific antibody can be measured in most of the serologic systems.* This most frequently involves detection of IgM in whole or fractionated sera. Numerous techniques are used to fractionate and then test the serum. An important consideration in any IgM assay is the possibility of false-positive results because of the presence of rheumatoid factor. Solid-phase IgM capture assays seem to be unaffected, however, by rheumatoid factor [103–106,221,236,247].

## GROWTH IN CELL CULTURE

Rubella replicates in a wide variety of cell culture systems, primary cell strains, and cell lines [157,161,250]. The time required for virus recovery varies markedly, depending partly on the culture system being employed.

Generally, rubella growing in primary cell cultures (i.e., human, simian, bovine, rabbit, canine, or duck) produces interference to superinfection by a wide variety of viruses (especially enteroviruses, but also myxoviruses, papovaviruses, arboviruses, and to some extent herpesviruses), but no cytopathic effect [19,20,156]. In contrast, a cytopathic effect of widely varying natures results from infection of continuous cell lines (i.e., hamster, rabbit, simian, and human). Generally, primary cells, especially African green monkey kidney, have proved superior for isolation of virus from human material by the interference technique. The continuous RK-13 and Vero (vervet monkey kidney) cell lines are also used, however, because cytopathic effect is produced, and there is no problem with adventitious simian agents [157]. Continuous cell lines, such as BHK-21 and Vero, are best suited for antigen production because of the higher levels of virus produced.

All cell lines support chronic infection with serial propagation, but some are limited by the occurrence of cytopathic effect. These cells grow slowly and can be subcultivated fewer times than when not infected [157]. The mechanisms of rubella-induced interference and persistent infection in cell cultures are not completely understood. Although interferon production has been described after rubella infection of cell cultures, interference seems to be an intrinsic phenomenon [157,161,251–253]. As with other viruses, generation of defective interfering particles can be found in tissue culture [254]. These particles are thought to be nonessential for persistence, however.

Rubella virus can be plaqued in RK-13, BHK-21, SIRC (i.e., rabbit cornea), and Vero cells [161]. Plaquing forms the basis of neutralization assays, and differences in plaquing characteristics can be used as markers to differentiate strains [21,161,178,206–208].

*References 161, 217–221, 224, 226, 235–238, 241–249.

## PATHOGENICITY FOR ANIMALS

Rubella virus grows in primates and in various small laboratory animals. The acquired or congenital disease has not been completely reproduced in any animal, however.

Vervet and particularly rhesus monkeys are susceptible to infection by the intranasal, intravenous, or intramuscular routes [255–257]. Although no rash develops, there is nasopharyngeal excretion of virus in all of the inoculated monkeys and demonstrable viremia in 50%. Attempts to produce transplacental infection in pregnant monkeys have been partially successful. Rubella virus has been recovered from the amnion and the placenta, but the embryo itself has not been shown to be consistently infected [258,259].

The ferret is the most useful of the small laboratory animals in rubella studies. Ferret kits are highly sensitive to subcutaneous and particularly to intracerebral inoculations. Virus has been recovered from the heart, liver, spleen, lung, brain, eye, blood, and urine for 1 month or longer after inoculation, and neutralizing and complement fixation antibodies have developed [260]. Ferret kits inoculated at birth develop corneal clouding. Virus appears in fetal ferrets after inoculation of pregnant animals [261].

Rabbits, hamsters, guinea pigs, rats, and suckling mice all have been infected with rubella virus, but none has proved to be a consistent and reliable animal model system for study of rubella infection [179,180,262–265]. Studies indicating that Japanese strains of rubella virus were less teratogenic to offspring of infected rabbits than U.S. strains have not been confirmed [179,180]. These experiments were conducted to examine further the hypothesis referred to earlier that there is a difference in the virulence among rubella virus strains circulating in Japan and other parts of the world [177,179–183,185].

# EPIDEMIOLOGY

Humans are the only known host for rubella virus. Continuous cycling in humans is the only apparent means for the virus to be maintained in nature. Because rubella is predominantly a self-limited infection seen in late winter and spring, questions have arisen about how the virus persists throughout the remainder of the year. Person-to-person transmission probably occurs at very low levels in the general population throughout summer and winter and probably at much higher levels in closed populations of susceptible individuals [266–287]. Congenitally infected infants can shed virus from multiple sites and can serve as reservoirs of virus during periods of low transmission [165,288–293]. This is of particular concern in the hospital setting [165,285]. Efficiency of transmission may also vary among individuals, with some being better “spreaders” than others. This phenomenon may contribute to continued circulation of the virus [294].

Rubella has a worldwide distribution [295–301]. The virus circulates almost continually, at least in continental populations. In the continental temperate zones of the Northern Hemisphere, rubella is consistently more prevalent in the spring, with peak attack rates in March, April, and May; infection is much less prevalent during the remainder of the year, increasing or decreasing during

the 2 months before or after the peak period [298,300]. Before widespread rubella immunization, sizable epidemics occurred every 5 to 9 years in temperate climates; however, the periodicity of rubella epidemics was highly variable in developed and developing countries, with major epidemics occurring at intervals ranging from 10 to 30 years. Epidemics usually built up and receded gradually over a 3- to 4-year interval, peaking at the midpoint [9,295,298,300].

The apparent increased infectivity and virulence of rubella as exemplified in the major epidemics have been the subject of considerable speculation. One popular thesis has been the unproven emergence of a more virulent strain of virus at widely separated intervals [177,179–183,185]. No convincing evidence exists concerning clinically different strains of rubella, however, and molecular analysis of the E1 envelope glycoprotein does not support the hypothesis of an epidemic versus endemic strain difference [84]. The apparent severity of the epidemic seems to be related to the number of susceptible adults, especially pregnant women, in any given population at the outset of an epidemic [184,186,300,302]. Host factors, such as the differences in the ability to transmit rubella, and still unknown factors may also be involved [294,302].

Attack rates in open populations have not been defined precisely for many reasons. Because rubella is such a mild disease, it is underreported, even in areas where reporting has been mandatory for years. Mandatory reporting did not begin in the United States until 1966 (Fig. 28–2) [298,303]. The high and variable rate of inapparent infection poses a major problem when attempting to interpret the recorded data, which are based usually on clinical findings [271,304–309].

In childhood, the most common time of infection, 50% or more of serologically confirmed infections result in inapparent illness. The ratio may be 6:1 or 7:1 in adults, perhaps as a result of silent reinfection in naturally immune individuals who have lost detectable antibody [271,307]. The frequent occurrence of infections that clinically mimic rubella makes it even more difficult to determine attack rates in open populations [310]. Attack rates undoubtedly depend on the number of susceptible individuals, which varies widely in different locations.

Serologic assessments of rubella attack rates have been performed in closed populations, such as military recruits, isolated island groups with small populations, boarding

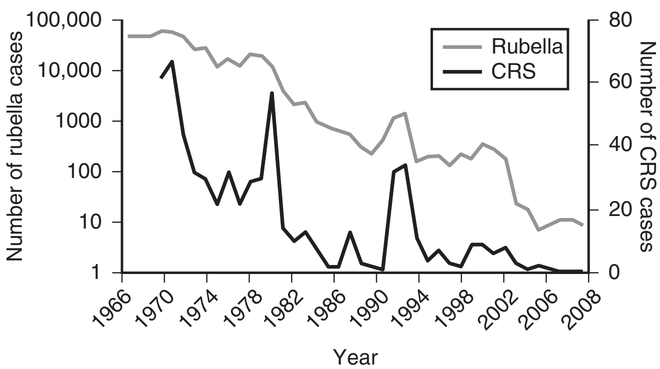

**FIGURE 28–2** Cases of rubella and congenital rubella syndrome (CRS) in the United States, 1996-2008. *(Data from Centers for Disease Control and Prevention, courtesy of S. Reef, 2009.)*

home residents, and household members [271–273,294,306,309–317]. In such situations, individual exposure to the virus is more intense than encountered in open populations. Under these circumstances, 90% to 100% of children and adults who are susceptible may become infected. Attack rates in susceptible persons on college and university campuses and in other community settings range from 50% to 90% [9,302]. Similar to primary infection, reinfection probably is increased as exposure becomes more intense [271,307,315,316].

In most of the world, including the United States before the introduction of mass immunization of children in 1969, rubella was typically a childhood disease that was most prevalent in the 5- to 14-year-old age group [2,3,7,296–303]. It was rare in infants younger than 1 year of age. The incidence increased slowly for the first 4 years, increased steeply between 5 and 14 years, peaked around 20 to 24 years, and then leveled off. In developed countries before mass immunization, the incidence of infection did not reach 100% before the ages of 35 to 40 years; 5% to 20% of women of childbearing age remained susceptible to infection.

In the era before a rubella vaccine, in isolated or island populations, such as in Trinidad, some areas of Japan, Panama, rural Peru, and Hawaii, a relatively high rate of susceptibility was found among young adults [296,297,299,300,313]; 26% to 70% of women of childbearing age remained susceptible. This situation existed even though rubella was endemic with ample opportunity for multiple introductions of virus from the outside. Low population density, tropical climate, low concentration of effective spreaders, and genetic factors all have been invoked to explain these low attack rates, but none can adequately account for this peculiar epidemiologic phenomenon by itself [294,299,300,302]. Later studies from 45 developing nations where rubella immunization efforts have been minimal have revealed a wide range of susceptibility (≤10% to approximately 25%) [314].

In other areas, particularly in South America, infections begin earlier in life, and peak incidence occurs before puberty [299]. Infection rates in most South American countries reach a plateau at approximately the same level as seen in Europe and North America, however, leaving 10% or more of young women who are susceptible, based on serologic tests. Chile seemed to be an exception, with almost all persons being infected before puberty [299]. The impact of major immunization programs in the PAHO countries to reach a goal of eliminating rubella by 2010 appears to have eliminated new infections to date. (http://new.paho.org/).

Initial mass vaccination of children with distribution of more than 29 million doses over the first year after licensure, followed by routine vaccination of 1-year-old children and vaccination of susceptible adolescents and adults, has been extremely successful in controlling rubella and CRS in the United States.* The characteristic 6- to 9-year epidemic cycle has been interrupted, and the reported incidence of rubella that ranged from approximately 200 to 400 cases annually during the period 1992–2000 decreased to less than 25 since 2001. For comparison,

*References 5, 24, 33, 39, 269, 303, 318.

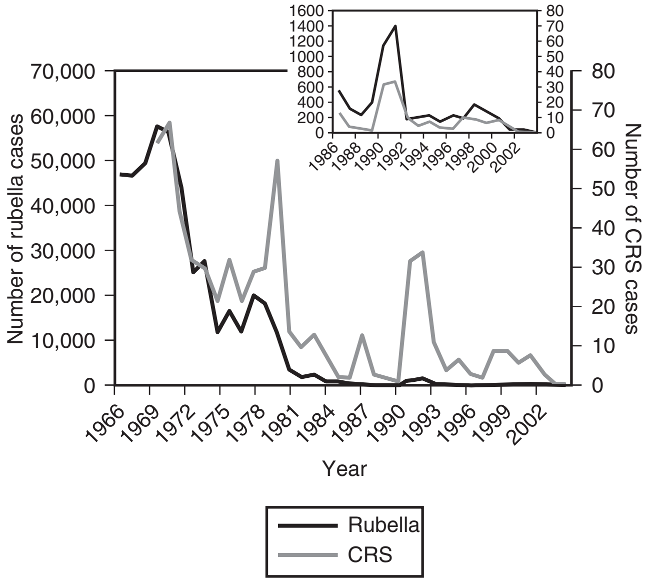

**FIGURE 28–3** Incidence rates for reported cases of rubella and congenital rubella syndrome (CRS) in the United States, 1966-2003. *(Data from Centers for Disease Control and Prevention, courtesy of S. Reef, March 1, 2004.)*

there were approximately 58,000 cases reported in 1969, the year of vaccine licensure in the United States (Fig. 28–3).

Age-specific declines in the occurrence of rubella have been greatest in children, who, because they were the major reservoir of the virus, have been the primary target of the U.S. immunization program. The risk of rubella decreased by 99% in all age groups, however, after efforts to increase vaccination levels in older, susceptible persons, especially women of childbearing age (see "Prevention of Congenital Rubella") [266,268]. Until the late 1990s, serologic surveys documented susceptibility of 20% in this adult population; however, the National Health and Nutrition Examination Survey (NHANES) (1999–2004) documented susceptibility of less than 11% [319–322].

Adolescents and young adults now account for most reported cases, with more cases reported among individuals older than age 15 years than in children. Although there are fewer and smaller outbreaks since elimination was achieved, outbreaks are still reported in colleges, cruise ships, and other settings in which people live or work in proximity [277–279,282–287]. Outbreaks no longer occur among military recruits because they receive rubella vaccine as soon as they arrive for basic training [274].

Although the reported incidence of cases of CRS has decreased dramatically, the number of cases of rubella and congenital rubella reported in the United States increased in 1989–1991, documenting that the potential for cases will continue as long as immunization of children and women of childbearing age is not close to 100% [39]. The outbreak of rubella and subsequent clusters of congenital rubella among the Amish in Pennsylvania in 1991 and 1992 provided a reminder that there are still pockets of susceptible individuals in the United States [281]. The epidemiology of rubella is closely linked with the epidemiology of CRS. From 1997–1999, more than 90% of the mothers of infants with CRS were born outside the United States. Since 2000, the incidence of CRS has been the lowest reported at a rate of less than 1 per 1 million live births and with most of the mothers of these infants born outside the United States and presumably unimmunized [323].

## TRANSMISSION IN UTERO

In pregnant women with clinical or inapparent primary rubella, the virus infects the placenta during the period of viremia and subsequently infects the fetus [2,6,295, 310,324–339]. Intrauterine transmission of virus associated with maternal reinfection is rare. It is presumed that this difference is a reflection that viremia is absent or greatly reduced because of immunity induced by the primary infection (natural or vaccine induced).* Maternal infection may result in no infection of the conceptus, resorption of the embryo (seen only with infections occurring in the earliest stages of gestation), spontaneous abortion, stillbirth, infection of the placenta without fetal involvement, or infection of the placenta and fetus [6]. Infected infants can have obvious multiorgan system involvement or, as is frequently observed, no immediately evident disease [6,13,111,340–347]. After long-term follow-up, many of these seemingly unaffected infants have evidence of hearing loss or central nervous system (CNS) or other defects.†

Gestational age at the time of maternal infection is the most important determinant of intrauterine transmission and fetal damage [2–4,6,295,310,327]. The risk of fetal infection and congenital anomalies decreases with increasing gestational age. Fetal damage is rare much beyond the first trimester of pregnancy, as was shown in large British and American studies (Table 28–1).

Availability of more sensitive antibody assays has led to refinement of understanding of the risk of fetal infection and subsequent congenital defects throughout all stages of pregnancy [107,114]. Although the risk of defects does

decrease with increasing gestational age, fetal infection can occur at any time during pregnancy. Data on the risk of fetal infection are inconsistent when maternal rubella infection occurs before conception [1,12,112,114, 348–351]. If some risk exists, it is small.

## RISK OF FETAL INFECTION

Early attempts to define the risk of fetal infection relied on isolation of virus from products of conception [324–330]. Of products of conception obtained from women with clinical rubella during the first trimester, 40% to 90% were found to be infected. The higher rates were observed in serologically confirmed cases of maternal rubella and when improved isolation techniques were employed [329,330]. Attempts were made to refine the risk estimates by evaluating placental and fetal tissue separately. In some of these studies, equal rates of persistent placental and fetal infection were observed, ranging from 80% to 90% [329,330].

In other studies, persistent placental infection was found to be twice as frequent as fetal infection: 50% to 70% versus 20% to 30% [324,327]. High rates of fetal infection accompanied placental infection, however, when specimens obtained during the first 8 weeks of gestation were examined. Of 14 cases in which virus was cultured from placental tissue, six of seven fetuses were culture-positive when maternal rubella occurred during the first 8 weeks of pregnancy. In contrast, only one of seven fetal specimens was positive when infection occurred between 9 and 14 weeks of gestation [324]. In another similar study, fetal infection rates decreased sharply after the 8th week of gestation; placental infection rates decreased, but less rapidly [327]. After the 8th week, placental infection occurred in 36% (8 of 22) and fetal infection occurred in 10% (2 of 20) of cases. Although fetal infection was not documented beyond the 10th week of gestation, placental infections were identified up to the 16th week.

Further data on the risk of fetal infection have been obtained from studies using sensitive laboratory tests to detect congenital infection in children born to mothers with serologically confirmed rubella [107,114]. Because congenital rubella is often subclinical in infants and young children, use of such tests is necessary to assess accurately the risk of congenital infection [6,107–112,341,343–346]. In investigations in which this approach was used, with detection of rubella-specific IgM antibody in sera to document congenital infection, the discrepancy between rates of placental and fetal infection seen in viral isolation studies is less apparent. These studies have provided new information on the events after maternal infection in the second and third trimesters.

In a study involving 273 children (269 of whom had IgM antibody assessment), Miller and colleagues [109] reported that fetal infection after serologically documented symptomatic maternal rubella in the first trimester was, as expected, quite high: 81% (13 of 16), with rates of 90% for fetuses exposed before 11 weeks and 67% for fetuses exposed at 11 to 12 weeks (Table 28–2). Of greater interest is that the infection rate was 39% (70 of 178) after exposure in the second trimester (decreasing steadily from 67% at 13 to 14 weeks to 25% at 23 to 26 weeks), but increased to 53% (34 of 64) with third-trimester infection (with infection rates of 35%, 60%, and 100% during the last 3 months of pregnancy).

In another investigation of fetal infection after first-trimester maternal rubella infection based on IgM determination, Cradock-Watson and associates [107] found that 32% of 166 children were infected after exposure in the second trimester and that a comparable proportion (24% of 100) were infected after exposure in the third trimester. The rate of infection increased during the latter stages of gestation after initially decreasing to a low of 12% by the 28th week and was 58% (11 of 19) when maternal infection occurred near term. Even higher rates were observed when persistence of IgG antibody was used

as the criterion for congenital infection. The true fetal infection rate probably lies between the rates calculated by using the IgM and persistent IgG data.

In both studies, the fetal infection rate declined between 12 and 28 weeks, suggesting that the placenta may prevent transfer of virus, although not completely [107]. Some of the infections recorded during the last weeks of pregnancy could have been perinatally or postnatally acquired (e.g., by means of exposure to virus in the birth canal or from breast milk), but the available evidence indicates that the placental barrier to infection may be relatively ineffective during the last month, perhaps to the same degree as that seen during the first trimester, and that the fetus is susceptible to infection throughout pregnancy, albeit to various degrees [352–354].

## RISK OF CONGENITAL DEFECTS

Estimates of the risk of congenital anomalies in live-born infants after fetal infection have been affected by numerous factors. Early retrospective and hospital-based studies led to overestimates of the risk of congenital defects after first-trimester infection (up to 90%) [6,111,302]. The risk of abnormalities as determined by prospective studies relying on a clinical diagnosis of maternal rubella varied considerably (10% to 54% overall, with a 10% to 20% risk for major defects recognizable in children ≤3 years old) and tended to underestimate the risk because serologic evaluation of infants was not performed [111,348, 355–359]. The proportion of pregnancies electively terminated can affect observed malformation rates. The fact that fetal infection can occur during all stages of pregnancy also influences assessments of the risk of congenital defects.

Because most infants born with congenital rubella who were exposed after the 12th week of gestation do not have grossly apparent defects, long-term follow-up is necessary to detect subtle, late-appearing abnormalities, such as deafness and mental impairment.* This is especially true for infants infected beyond the 16th to 29th week of gestation, who seem to be at little, if any, risk of congenital anomalies [107,113]. Studies by Peckham [111,345] showed that estimates of the risk of defects are affected by the serologic status and age at evaluation of the child. The overall incidence of defects in 218 children studied when they were about 2 years old was 23%; it was 52% if maternal infection occurred before 8 weeks of gestation, 36% at 9 to 12 weeks, and 10% at 13 to 20 weeks. No defects were observed when maternal infection occurred after 20 weeks. When considering only seropositive children, the overall risk of defects increased to 38%, with increased risks of 75%, 52%, and 18% for the three gestational periods previously cited. At follow-up when the children were 6 to 8 years old, the overall risk of abnormalities in infected children who were seropositive when 2 years old increased from 38% to 59%; the risk after first-trimester infection increased from 58% to 82%.

Miller and colleagues [109] observed higher rates of defects in infected children observed for only 2 years (see Table 28–2). Defects were seen in 9 of 9 seropositive children exposed during the first 11 weeks of gestation, 2 of 4 children exposed at 11 to 12 weeks, 2 of 12 children exposed at 13 to 14 weeks, and 7 of 14 children exposed at 15 to 16 weeks. Congenital heart disease and deafness were observed after infection before the 11th week; deafness was the sole defect identified after infection at 11 to 16 weeks of gestation. No defects were observed in 63 children infected after 16 weeks of gestation. Some children infected in the third trimester had growth restriction, however.

Although the number of subjects is small, results of the study of Miller and colleagues [109] indicate that the risk of damage is 85% in infants who were infected as fetuses during the first trimester and 35% after infection during weeks 13 to 16. These rates of defects are higher than previously reported, but they may be an accurate reflection of intrauterine events because all maternal cases were serologically confirmed, and sensitive antibody assays were used to detect congenital infection. With further follow-up, higher rates of defects may be observed.

These rates pertain to offspring known to be infected and are useful in evaluating the risk of defects given fetal infection. For counseling purposes, it is essential to know the risk of congenital defects after confirmed maternal infection. This risk can be derived by multiplying the rates of defects in infected fetuses by the rates of fetal infection. Based on the reported experience of Miller and colleagues [109], the risks are 90% for maternal infection before the 11th week of gestation, 33% for infection during weeks 11 to 12, 11% for weeks 13 to 14, and 24% for weeks 15 to 16 (see Table 28–2). The overall risk after maternal infection in the first trimester was 69%.

# NATURAL HISTORY

## POSTNATAL INFECTION

### Virologic Findings

The pertinent virologic findings of postnatal infection are depicted in Figure 28–4. The portal of entry for rubella virus is believed to be the upper respiratory tract. Virus spreads through the lymphatic system, or by a transient viremia to regional lymph nodes, where replication first occurs. Virus is released into the blood 7 to 9 days after exposure and may seed multiple tissues, including the placenta. By the 9th to 11th day, viral excretion begins from the nasopharynx, kidneys, cervix, gastrointestinal tract, and various other sites.*

The viremia peaks at 10 to 17 days, just before rash onset, which usually occurs 16 to 18 days after exposure. Virus disappears from the serum in the next few days, as antibody becomes detectable [289,305,312,360]. Infection may persist, however, in peripheral blood lymphocytes and monocytes for 1 to 4 weeks [63,68,361,362]. Virus is excreted in high titers from nasopharyngeal secretions. Nasopharyngeal shedding rarely may be detected for 3 to 5 weeks. Although virus can usually be cultured from the nasopharynx from 7 days before to 14 days after rash onset, the highest risk of virus transmission is believed to be from 5 days before to 6 days after the appearance of

rash. Viral shedding from other sites is not as consistent, intense, or prolonged [305,360]. Rubella virus has been cultured from skin at sites where rash was present and where it was absent [363,364].

## Humoral Immune Response

In challenge studies conducted in the early 1960s, Green and coworkers [305] showed that neutralizing antibody was first detected in serum 14 to 18 days after exposure (usually 2 to 3 days after rash onset), peaked within 1 month, and persisted for the duration of the follow-up period of 6 to 12 months. The HI test soon became the standard method for detecting rubella antibodies after acute postnatal rubella infection because of its reliability and ease compared with the neutralization test. Several other methods for measuring rubella antibody responses have supplanted the HI test in popularity (see "Virus") [92,210,211]. Figure 28–5 depicts the kinetics of the immune response to acute infection detected by these various serologic assays, which have been exhaustively compared with the HI technique.*

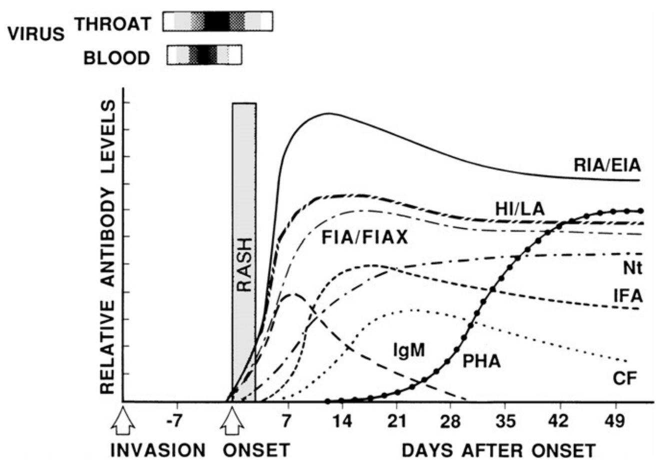

**FIGURE 28–5** Schematic diagram of immune response in acute rubella infection. CF, complement fixation; EIA, enzyme immunoassay; FIA/FIAX and IFA, immunofluorescence assays; HI, hemagglutination inhibition; LA, latex agglutination; Nt, neutralization; PHA, passive agglutination; RIA, radioimmunoassay. *(Data from Herrmann KL. Rubella virus.* In *Lennette EH, Schmidt NJ [eds]. Diagnostic Procedures for Viral, Rickettsial and Chlamydial Infections. Washington, DC, American Public Health Association, 1979, p 725; and Herrmann KL. Available rubella serologic tests. Rev Infect Dis 7[Suppl 1]:S108, 1985.)*

There are generally three distinct patterns of antibody kinetics. Antibodies of the IgG class measured by HI, latex agglutination, neutralization, immunofluorescence, single radial hemolysis (or hemolysis in gel) (not shown in Fig. 28–5), radioimmunoassay, and enzyme-linked immunoassay theta precipitation (not shown) follow the first pattern. These IgG antibodies usually become detectable 5 to 15 days after rash onset, although they may appear earlier and may even be detected 1 or 2 days before the rash appears. The antibody titers rapidly increase to reach peak values at 15 to 30 days and then gradually decline over years to a constant titer that varies from person to person. In some patients with low levels of residual antibody, a second exposure to rubella virus may lead to low-grade reinfection of the pharynx. A booster antibody response can be detected with any of the assays. This antibody response rapidly terminates the new infection, which is most often subclinical, and little or no viremia occurs.†

A second pattern of immune response to rubella infection is seen when IgG antibodies are measured by passive hemagglutination. The peak titer of these antibodies is similar to that measured by HI, but the passive hemagglutination antibodies are relatively delayed in appearance, and levels increase only slowly to their maximal titers. They first become detectable 15 to 50 days after the onset of the rash and often take 200 days to reach peak titers. The antibodies probably persist for life. Booster responses may be seen with reinfections.

Studies indicate that the predominant IgG subclass detected by all these various assays is probably IgG1 [99,101]. Failure to detect IgG3 may be indicative of reinfection [102].

A third distinct pattern of antibody production is represented in Figure 28–5 by the IgM antibody class immune response. Rubella-specific IgM antibody can be measured by HI, immunofluorescence, radioimmunoassay, or enzyme immunoassay.‡ IgM antibodies are most consistently detectable 5 to 10 days after the onset of the rash, increase rapidly to peak values at around 20 days, and then decline so rapidly that they usually disappear by 50 to 70 days. In a few patients, low levels may persist for 1 year [365–367]. The booster IgG antibody response to reinfection described earlier does not usually involve the IgM class of antibody, and the presence of high-titer IgM antibodies usually indicates recent primary infection with rubella. More sensitive techniques, such as radioimmunoassay or enzyme immunoassay, may occasionally detect low levels of specific IgM antibodies in some patients with reinfections, which may cause some difficulty in differentiating subclinical reinfection, which is almost always of no consequence, from acute primary subclinical infection [45,55,57,59]. Determination of avidity of rubella-specific IgG may help resolve this problem [368–370]. Primary infection seems to be associated

*References 92–96, 202, 206–216, 218, 225–235, 237, 240.

†References 42, 48, 51, 54, 58, 60, 271, 316, 339.

‡References 103, 161, 217–221, 224, 226, 235, 236.

with low-avidity IgG, and reinfection seems to be associated with high-avidity IgG.

The kinetics of the immune response to rubella infection detected by other serologic assays is not as distinct as the three patterns just described, and marked variability among patients has been observed. Complement fixation antibodies or iota precipitins (not shown in Fig. 28–5) are lacking in the first 10 days after the rash and increase slowly to peak at 30 to 90 days [202]. These antibodies persist for several years in one third of patients and may reappear during reinfections. Iota precipitins do not persist for more than a few months and do not usually reappear with reinfections.

Antibodies of the IgA class appear within 10 days, but may disappear within another 20 days or persist for several years [100,103,217,242]. IgD and IgE antibodies appear rapidly (6 to 9 days) after infection, remain high for at least 2 months, and then decline slightly at 6 months [100]. IgE antibodies reach an early peak similar to that seen for IgM and IgA. In contrast, the IgD response is, delayed, similar to that of IgG.

The antibody response after infection is generally considered to confer complete and permanent immunity. Clinical reinfection is rare, and reinfections usually pose little risk to the fetus because placental exposure to the virus is minimal.* Some rare instances of fetal infection after maternal reinfection may be caused by an incomplete immune response to the various antigenic domains on each structural protein of the virus (see “Virus”) [78–80,115,119,331,336–340]. Three cases after natural infection have been reported involving women who had positive HI results, but who had no detectable levels of neutralizing antibody [331,336,338]. The sensitivity of the neutralizing assay itself is an important determinant in interpreting these results [115,207]. This phenomenon also may account for the four reported cases of congenital infection that followed reinfection of women who had presumably been immunized previously [46,49,56,120]. Some reported instances of maternal reinfection probably (and in at least one case definitely) represent cases of primary acute infection [5,6,117,333–335].

## Cellular Immune Response

Cellular immunity to rubella virus has been measured by lymphocyte transformation response, secretion of interferon, secretion of macrophage migration-inhibitory factor, induction of delayed hypersensitivity to skin testing, and release of lymphokines by cultured lymphocytes [371–382]. Peripheral blood lymphocytes from seropositive individuals respond better in each of these tests than do lymphocytes from uninfected persons, suggesting that these assays measure parameters of the cellular immune response to rubella virus. The results from other studies in which chromium 51 microcytotoxicity assays have been used are difficult to interpret because syngeneic cell lines have not been used to control for HLA-restricted responses [372,375].

In the first weeks after natural rubella infection, some degree of transient lymphocyte suppression may occur [376,378]. Generally, cell-mediated immune responses precede the appearance of humoral immunity by 1 week, reach a peak value at the same time as the antibody response, and subsequently persist for many years, probably for life [341]. Acute infection may suppress skin reactivity to tuberculin testing for approximately 30 days [383].

## Local Immune Response

The local antibody response at the portal of entry in the nasopharynx is essentially IgA in character, although IgG antibody from serum may diffuse into nasopharyngeal secretions. The nasopharyngeal IgA antibody persists at detectable levels for at least 1 year after infection. Its persistence apparently minimizes the tendency for reinfection after natural rubella infection. The lack of local IgA nasopharyngeal response after parenteral administration of live rubella vaccines (less so with the RA 27/3 strain than with other strains) probably plays a key role in the increased incidence of subclinical reinfection after vaccination.* Local antibody levels tend to be higher in individuals resistant to challenge with live virus, but no specific titer of antibody has been associated with complete protection.

A cell-mediated immune response in tonsillar cells has been detected by lymphocyte transformation and secretion of migration-inhibitory factor after natural rubella and after intranasal challenge with live RA 27/3 vaccine [388]. In guinea pigs, the response first becomes detectable 1 to 2 weeks after intranasal vaccination, peaks at 4 weeks, and disappears at about 6 weeks [389].

# CONGENITAL INFECTION

## Virologic Findings

An important feature that distinguishes congenital infection from postnatal infection is that the former is chronic.† During the period of maternal viremia, the placenta may become infected and transmit virus to the fetus (see “Transmission In Utero”) [2,6,295,310,324–330]. Although virus may persist for months in the placenta, recovery of virus from the placenta at birth occurs infrequently [392]. In contrast, after the fetus is infected, the virus persists typically throughout gestation and for months postnatally. It can infect many fetal organs or only a few [327].

In infected infants, virus can be recovered from multiple sites (e.g., pharyngeal secretions, urine, conjunctival fluid, feces) and is detectable in cerebrospinal fluid, bone marrow, and circulating white blood cells.‡ Pharyngeal shedding of virus is more common, prolonged, and intense during the early months after delivery (Fig. 28–6). By 1 year of age, only 2% to 20% of infants shed virus [288–290]. Rarely, shedding may continue beyond the age of 2 years [291–293]. Virus can be isolated from the eye and cerebrospinal fluid, particularly when disease is evident in the corresponding organs and can persist for more than 1 year in the eye and CNS [393–396]. Virus has been isolated

from the brain of a 12-year-old boy with later appearing subacute panencephalitis occurring after congenital rubella infection [395,397,398].

## Humoral Immune Response

Studies have shown that placental infection does not prevent passive transfer of maternal antibody and that the infected fetus can mount an immune response [295, 324–330,399–401]. Although the development and function of the other components of the immune response of the fetus may be important, critical factors that allow fetal infection to occur in the presence of antibody may be the timing when antibody is present in the fetal circulation, the quality of the antibody that the fetus produces, or both.

Although placental transfer of antibody occurs despite persistent infection, levels of antibody in fetal blood during the first half of gestation are only 5% to 10% of levels in maternal serum [402,403]. As the placental transfer mechanisms mature by mid-gestation (16 to 20 weeks), increasing levels of maternal IgG antibody are transferred to the fetus (Fig. 28–7) [404,405].

The development of the fetal humoral immune system apparently is too late to limit the effects of the virus. Cells with membrane-bound immunoglobulins of all three major classes—IgM, IgG, and IgA—appear in the fetus by 9 to 11 weeks of gestation [403]. Circulating fetal antibody levels remain low until mid-gestation, however, despite the presence of high titers of virus and the development of antigen receptors on the cell surface (see Fig. 28–7). At this time, levels of fetal antibody increase, with IgM antibody predominating [399,406–410]. Fetal IgA, IgD, and IgG also are made, although in lesser amounts [100,407,410]. As in the case with other chronic intrauterine infections, congenital rubella infection may lead to an increase in total IgM antibody levels [399,401,405,410]. Total IgA levels are also occasionally increased, but IgG levels seldom exceed levels of uninfected infants [399,410–412]. At the time of delivery of infected infants, levels of IgG rubella antibodies in cord sera are equal to or greater than levels in maternal sera, even if the infant is born prematurely [399]. IgG is the dominant antibody present at delivery in rubella-infected infants and is mainly maternal in origin. In contrast, the IgM levels are lower, but are totally fetus derived.

In the first 3 to 5 months after birth, the levels of maternally derived IgG decrease as maternal antibody is catabolized (see Fig. 28–7) [399]. In contrast, IgM antibodies increase in titer and can predominate. Later, as viral excretion wanes and disappears, the IgM antibody levels diminish, and IgG becomes the dominant and persistent antibody type. Cradock-Watson and colleagues [410] found that total IgM was elevated in nearly all sera obtained from infected infants during the first 3 months of life and in half of sera from infected infants 3 to 6 months old. Rubella-specific IgM has been shown consistently to persist for 6 months, frequently for 1 year, and rarely longer when assayed by sensitive serologic procedures, such as radioimmunoassay and immunofluorescence [223,410]. Cradock-Watson and colleagues [410] also reported that IgM was detectable in 48 (96%) of 50 serum samples during the first 6 months of life and in 11 (29%) of 38 serum samples from children 6.5 months to 2 years old. The total level of antibody, as measured by various serologic tests, remains virtually unchanged throughout the 1st year of life, despite the fluctuations in immunoglobulin composition [399,410].

High levels of IgG antibody are usually maintained for several years after detectable virus excretion ends, suggesting that there may be continued antigenic stimulation. During the first few years of life, some patients have a relative hypergammaglobulinemia, particularly of the IgM and IgG classes of antibody, which results from the increased antigenic stimulus accompanying the chronic infection [405,410]. With increasing time,

antibody levels may decrease and even become undetectable in 10% to 20% of patients [345,413–415]. Cooper and coworkers [415] found that the geometric mean HI titer decreased by a factor of 16 by age 5 years in 223 children with CRS. No HI antibodies were detected in 8 of 29 5-year-old children. In a study from Japan, only 3% of 381 children with congenital infection observed for more than 17 years had undetectable HI titers [416]. There was an initial rapid decline from a geometric mean titer of 1:416 ($2^{8.7}$) to 1:84 ($2^{6.4}$) over the first 2 years of follow-up. After this, there was a modest continuing decline, and the final geometric mean titer was 1:42 ($2^{5.4}$).

Cooper and coworkers [415] reported that congenitally infected children who have lost detectable rubella-specific antibody did not develop a boost in antibody titer after rubella vaccination. This finding may reflect some sort of immunologic tolerance that follows intrauterine exposure to rubella virus. None of the children with congenital rubella in Japan had evidence of significant boosts in antibody or a history of clinical disease when exposed during recent outbreaks of rubella [416,417]. RA 27/3 vaccine virus administered intranasally succeeded in inducing an immune response, however, so the problem may be less tolerance than low systemic levels of humoral or cellular immunity [415].

Hypogammaglobulinemia with low levels of all three major classes of immunoglobulins has been reported in a few instances of congenital rubella [137,165,418,419]. Usually, only IgA is affected; there may also be instances when IgG levels are low, whereas levels of IgM are two or three times the upper limit of normal for adults. These IgG and IgM abnormalities may occur with or without IgA abnormalities [418]. Over time, immunoglobulin development may become normal, and this can occur despite continued viral excretion, but is more likely if viral titers are decreasing [291].

In addition to defects in the immunoglobulin levels, defects in specific antibody production have been observed. One such defect is a complete lack of antibody response to any antigen, including the rubella virus itself. Response only to the virus, in the absence of a response to most other antigens, has also been reported [291]. This state of immunologic unresponsiveness resolves in many patients. Antibody production becomes normal as the patient's general condition improves and as immunoglobulin levels normalize.

Immunoprecipitation studies of sera from patients with CRS provide further information on defective antibody production. The studies indicate that the antibody profile to the three structural proteins of the rubella virus is qualitatively different from that observed in sera from persons with postnatally acquired infection (see "Virus") [88,89,91]. Little or no antibody to the core structural protein (C) is found, and the absolute and relative amounts of antibody to structural proteins E1 and E2 seem to vary with age [88,89]. These findings further suggest that the immune response of the infected fetus may be incomplete and may explain why detectable antibodies are not present in some serum samples [91,345,413–416]. If a serum sample contains relatively little antibody to structural protein E1 (i.e., hemagglutinin), assays that detect antibody to the whole virion are more likely to be positive than assays that detect antibody only to E1 (e.g., HI assay). It is unclear whether these abnormal antibody patterns persist for life.

## Cellular Immune Response

Similar to the cells responsible for the humoral immune response (i.e., B cells), the cells involved in cellular immunity (i.e., T cells and macrophages) develop some of their functions early in gestation [420–422]. Little is known about their response in utero, however, because appropriate specimens have not been obtainable for study. The cellular immune response of the infected fetus has been inferred from studies of infected infants and children. Available evidence indicates that some infants with congenital rubella have impaired cellular immune responses.

Retarded development of the thymus and lymphocyte depletion have been reported, but these abnormalities may result from the stress of infection, rather than the virus itself [423]. Abnormal delayed hypersensitivity skin reactions to numerous antigens (e.g., diphtheria toxoid, *Candida*, dinitrofluorobenzene) have also been reported [291,424]. This defect has been associated with abnormalities in the humoral system and resolves as antibody production returns to normal.

Results of studies of in vitro lymphocyte blastogenesis in congenitally infected infants and children have been confusing. Early studies showed a poor response to phytohemagglutinin, vaccinia, and diphtheria toxoid [424–427]. Because rubella virus can depress the lymphocyte blastogenic response, and the virus can be isolated from lymphocytes of chronically infected infants, the abnormality may be a result of viral infection of the circulating blood cells, rather than an inherent defect in cell-mediated immunity [425,426,428,429]. This diminished cellular response may normalize over time because elevated lymphocyte responses have been detected in some older infected children [420,430].

Buimovici-Klein and colleagues [382,431] showed that lymphocytes from older children and adolescents with congenital rubella had no or very poor lymphocyte proliferative responses to rubella virus antigens and had markedly reduced interferon and migration-inhibition factor production. These studies indicated that these defects were greater in children exposed early in gestation than those exposed later, with the greatest degree of abnormality in children whose mothers had been infected during the first 8 weeks of pregnancy. The studies also pointed out that these defects could persist long after viral excretion had ceased. It remains unclear if these cellular immune defects are responsible for viral persistence or are yet another manifestation of intrauterine infection [431].

Other investigators have confirmed that patients with congenital rubella have defects in cell-mediated immunity [124,137,138]. Verder and colleagues [138] reported a decreased proportion of suppressor or cytotoxic ($CD8^+$) T cells in an infant with congenital rubella. Rabinowe and coworkers [137] documented persistent T-cell abnormalities in patients with congenital infection who were 9 to 21 years old. Compared with normal subjects, congenitally infected patients had depressed ratios of T4 cells (helper or inducer) to T8 cells (from a decreased

proportion of T4 and an increased percentage of T8 cells). Such findings persist for only 1 month after acute postnatal rubella infection [432].

Lymphocytes of infected children were unable to kill rubella-infected cells in a cytotoxicity assay [433]. These results were questioned because syngeneic target cells were not used, and these responses are known to be HLA restricted. Similar results have been reported by Verder and associates [138], however, who observed abnormal killer and natural killer cell activities.

Morag and associates [389] detected cytotoxic T lymphocytes in tonsillar lymphocytes after intranasal administration of RA 27/3 vaccine, but not after subcutaneous administration of another attenuated strain. Elevation of cytokines interleukin-4, interleukin-10, and tumor necrosis factor-α after vaccination has also been observed [434].

### Interferon Response

It has long been suggested that the fetus has a deficient interferon response to viral infections, including rubella, but this evidence has been derived from indirect studies with in vitro cell systems or animal models [182,183, 329,435,436]. Technical difficulties have hampered direct studies of humans. Interferon that seemed to be specifically stimulated by the presence of rubella virus in rubella-infected human embryos has been shown, however [437]. The interferon was found at 7 weeks of gestation and persisted 12 weeks after symptoms ceased in the mothers. Direct study of fetal blood and amniotic fluid has also shown that the fetus can produce interferon in response to the virus [438].

Children with congenital infection have the capacity to make interferon on challenge. Desmyter and coworkers [439] reported that interferon could not be detected from the serum or urine of nine children 11 to 18 months old who were excreting virus. After vaccination with live measles vaccine (i.e., Edmonston B or Schwarz strains), all the children seroconverted, however, and produced detectable levels of interferon.

# PATHOGENESIS

## POSTNATAL INFECTION

The events leading to acute postnatal infection are relatively well known and have been discussed in detail in "Natural History." Available information indicates that viral replication and postinfection immune phenomena are involved in the clinical manifestations of the illness.

Viremia may lead to seeding of multiple organs, but few are clinically affected [6]. Speculation that the rash may be an immune phenomenon caused by circulating immune complexes has not been documented. Few persons with uncomplicated illness have immune complexes containing rubella virus, and virus has been isolated from involved and uninvolved skin [127,132,363,364]. Virus has been isolated from lymph nodes and conjunctiva, accounting for the lymph node enlargement and conjunctivitis observed in many patients [360,440]. Virus has been isolated from synovial fluid, but immune mechanisms may play a role in some cases of arthralgia and arthritis, particularly if symptoms are persistent [127,440–444]. Encephalitis is probably a manifestation of the immune response, but direct viral invasion may be involved, particularly in the rare case of progressive panencephalitis that has been reported to follow postnatal infection [125,445–447]. It has been suggested that pregnant women are at increased risk of serious complications because of the impaired immune response associated with pregnancy, but there are few data to support this claim [447–449]. There has also been interest, especially in Japan, in the influence of HLA type and other genetic factors on the incidence and severity of postnatal infection.* No consistent pattern has been reported.

## CONGENITAL INFECTION

The outcome of maternal rubella infection follows a logical sequence of events, beginning with maternal infection, followed by viremia, placental seeding, and dissemination of infection to the fetus (see "Transmission In Utero" and "Natural History") [2,6,295,310,324–330]. The fetus may escape infection entirely, die in utero, be born with multiple obvious defects, or seem to be normal at birth only to develop abnormalities later in life [6,13,111,289, 340–347]. The variability in outcome is highlighted by the observation that one identical twin may be infected and the other spared [6,451,452].

The most important determinant of fetal outcome is gestational age at the time of infection.† The disease is more severe and has a greater tendency to involve multiple organs when acquired during the first 8 weeks of gestation. The factors that govern the influence of gestation are unknown. It is possible that immature cells are more easily infected and support the growth of virus better than older, more differentiated cells. It is also possible that the placenta becomes increasingly resistant to infection (or at least more able to limit infection) as it rapidly matures during the first trimester. A third possibility is that maturing fetal defense mechanisms become capable of confining and clearing the infection. This last explanation is probably important after 18 or 20 weeks of gestation, but seems unlikely in the latter half of the first trimester, when attenuation of fetal infection begins. It is likely that a combination of these and other factors are responsible for the decrease in virulence of fetal infection with increasing gestational age.

The hallmark of fetal infection is its chronicity, with the tendency for virus to persist throughout fetal life and after birth.‡ The fact that virus can be isolated long after birth also raises the possibility of reactivation, at least in brain tissue [398]. It is unclear why the virus has these properties because the fetus is not truly immunologically tolerant and seems to be able to produce interferon.§ In any case, chronic or reactivated infection can lead to ongoing pathologic processes.‖

The causes of cellular and tissue damage from congenital rubella infection are poorly defined [435,436]. Only a

variable, small number of cells are infected (1 per 1000 to 250,000) [330]. In tissue culture, infection with rubella virus has diverse effects, ranging from no obvious effect to cell destruction (see "Virus"); this is also likely to be the case in vivo [161], but cytolysis is uncommon (see "Pathology") [2,3,6,9,453–457]. Inflammation is minimal and consists mainly of infiltration of small lymphocytes. Polymorphonuclear leukocytes and plasma cells are lacking, particularly compared with other viral infections of the human fetus, in which inflammation and general necrosis are quite extensive. In contrast, vascular insufficiency seems to be more important than cell destruction or secondary inflammatory damage in the genesis of congenital defects [2,3,6,9,453–457]. This suggestion is supported by the observation that rubella virus has low destructive potential for cells growing in vitro, including those of human origin. Numerous investigators have maintained multiple types of rubella-infected human fetal cells in culture for years without loss of viability or evidence of cytopathic effect [458–460].

Other defects have been reported in chronically infected cells that might help explain the mechanism of congenital defects. These include chromosomal breaks, increased cellular multiplication time, and increased production of a protein inhibitor that causes mitotic arrest of certain cell types [390,458,461–466]. The mitotic arrest is presumably responsible for the reduced replication of infected cells.

A report by Bowden and associates [467] indicates that rubella virus may interfere with mitosis by having an adverse effect on actin microfilaments. Observations of Yoneda and coworkers [468] show that rubella virus may alter cell receptors to specific growth factors. All of these abnormalities, if occurring in vivo, may result in decreased cell multiplication because of slow growth rates and limited doubling potential during the period of embryogenesis, when cell division and turnover are normally very rapid. Naeye and Blanc [469] found histopathologic evidence for mitotic arrest and reduced cell numbers in infants who died of CRS. These observations have been offered to explain the increased incidence of intrauterine growth restriction seen in infants with congenital rubella, but this explanation probably represents an oversimplification of the actual mechanisms involved.

More recently, it has been shown that rubella virus capsid protein interacts with host cell proteins to inhibit translation [469a]. Although infection of adult human cells often results in apoptosis, infection of fetal cells does not [469b]. The reduction of apoptosis would favor the chronic infection that is the hallmark of congenital rubella. Excess cytokine stimulation from persistent infection may also play a role.

Immunologic responses also have been proposed as causes of cellular damage. Although cellular immune defects may be a result of chronic infection, it is possible that these defects contribute to ongoing tissue damage [382,427,431]. Excessive serum immunoglobulin development, persistent antibody production in the face of viral replication for prolonged periods, and production of rheumatoid factor, all indicative of overstimulation of the immune system, also may have a role in the pathogenesis of CRS [470,471]. The presence of immune complexes and autoantibodies and the influence of certain HLA types may contribute to the delayed expression of some signs of congenital rubella, such as pneumonitis, diabetes mellitus, thyroid dysfunction, and progressive rubella panencephalitis (see "Clinical Manifestations").* Some of these immunologic events may be directly involved in tissue damage (e.g., immune complexes, autoantibodies), whereas others may allow the virus to persist or reactivate.

# PATHOLOGY

## POSTNATAL INFECTION

Little is known about the pathology of postnatally acquired rubella because patients seldom die of this mild disease. As observed by Cherry [9], the histologic findings of tissues that have been examined (i.e., lymph nodes and autopsy specimens from patients dying with encephalitis) are unremarkable. Changes in lymphoreticular tissue have been limited to mild edema, nonspecific follicular hyperplasia, and some loss of normal follicular morphology. Examination of brain tissue has revealed diffuse swelling, nonspecific degeneration, and little meningeal and perivascular infiltrate.

## CONGENITAL INFECTION

In contrast to the situation with postnatal rubella, much is known about the pathology of congenital rubella infection.† Generally, small foci of infected cells are seen in apparently normal tissue. Cellular necrosis and secondary inflammation are seldom obvious, although a generalized vasculitis predominates (see "Pathogenesis").

The pathologic findings of the placenta include hypoplasia, inflammatory foci in chorionic villi, granulomatous changes, mild edema, focal hyalinization, and necrosis [453,454,472,473]. Disease usually causes extensive damage to the endothelium of the capillaries and smaller blood vessels of the chorion. The vessel lesions consist mainly of endothelial necrosis, with fragmentation of intraluminal blood cells. Töndury and Smith [453] postulated that emboli of infected endothelial cells originating from the chorion might seed target organs in the fetus. These emboli may also contribute to organ damage by obstructing the fetal blood supply. Petechiae and the presence of hemosiderin-laden phagocytes in surrounding tissue are evidence of functional vascular damage [454].

Although not nearly as common as vascular lesions, specific cytolysis, presumably caused by direct viral effect on the cell, is also present in the placenta. This condition is characterized by cytoplasmic eosinophilia, nuclear pyknosis or karyorrhexis, and cellular necrosis. Specific nuclear and cytoplasmic cellular inclusion bodies are rare, but have been observed [473]. Although placentitis would be expected to be present in all affected placentas, regardless of when fetal infection occurred, Garcia and colleagues [473] found that placental lesions seemed to be more intense when infection occurred in the last trimester

*References 13, 14, 121, 124, 125, 127, 129, 130, 133–138, 398, 411.

†References 2, 3, 6, 9, 453–457, 472.

of pregnancy. This finding is consistent with the observation that the placenta is not a barrier to fetal infection in the latter stages of pregnancy [107,113,343,345].

Autopsies show that virtually every organ may be involved, with hypoplasia being a common finding. The necrotizing angiopathy of small blood vessels seen in the placenta is the most characteristic lesion in fetal organs. Cytolysis with tissue necrosis and accompanying inflammatory changes is also far less common, but has been found in the myocardium, brain, spinal cord, skeletal muscle, viscera, and epithelial cells of the developing lens, inner ear (organ of Corti), and teeth.

The overall pathologic process of congenital rubella, in keeping with its chronic nature, is progressive. Healing and new lesions can be found in specimens obtained in the later stages of gestation [453,454]. The pathologic changes vary among embryos in quantity and in organ distribution, and the location and nature of organ lesions depend on the gestational age at the time of infection [453]. The pathologic findings parallel the enormous variability of the clinical disease seen in infected newborns.

# CLINICAL MANIFESTATIONS

## POSTNATAL INFECTION

Rubella is usually a mild disease with few complications. Clinical illness may be more severe in adults.* Measles, varicella, and some enteroviruses acquired close to delivery may be associated with serious illness in the newborn, probably because of fetal exposure to transplacental viremia in the absence of protective levels of maternal antibody. One case report suggests that the same may be true in rubella. Sheinis and associates [475] reported the death of a neonate with rash onset when 12 days old; the mother developed rash on the day of delivery. This single observation needs to be confirmed. There are no conclusive data to indicate that infection in the immunocompromised host is associated with an increased risk of complications.

The first symptoms of rubella occur after an incubation period of 16 to 18 days (range 14 to 21 days). In a child, rash is often the first sign detected. In adolescents and adults, the eruption is commonly preceded by a 1- to 5-day prodromal period characterized by low-grade fever, headache, malaise, anorexia, mild conjunctivitis, coryza, sore throat, cough, and lymphadenopathy usually involving suboccipital, postauricular, and cervical nodes.

The constitutional symptoms often subside rapidly with the appearance of the rash. The rash can last 1 to 5 days or longer and can be pruritic in adults. Infection without a rash is quite common. The ratio of subclinical to clinical infections has varied from 1:9 to 7:1 [271,307]. Subclinical infection can lead to fetal infection, although it is unclear whether the risk is as great as that associated with clinically apparent infection.†

Arthralgia and frank arthritis with recrudescence of low-grade fever and other constitutional symptoms may appear after the rash fades. Joint involvement typically lasts 5 to 10 days, but may be more persistent. The frequency of these symptoms is variable, but they are more common in adults, particularly women [9]. In some studies of adult patients, the frequency has been 70% [476]. Thrombocytopenia (occurring in approximately 1 of 3000 patients) and acute postinfection encephalitis (occurring in 1 of 5000 to 6000 patients) are rare complications that usually occur 2 to 4 days after rash onset [9]. Rare complications associated with postnatal rubella include myocarditis, Guillain-Barré syndrome, relapsing encephalitis, optic neuritis, and bone marrow aplasia [9,477–481]. In a rubella outbreak in the Tongan islands, encephalitis was particularly frequent [482]. Two cases of a progressive panencephalitis, similar to measles-associated subacute sclerosing panencephalitis, have been reported [445,446]. This CNS disturbance is more likely to manifest in patients with CRS, although it still occurs infrequently [398,483,484]. Testalgia has also been reported in patients with rubella, but this may have been a coincidental finding [485,486].

An ophthalmic disease called Fuchs heterochromic cyclitis, a form of uveitis, has been associated more recently with rubella virus infection [487–491]. The disease usually affects only one eye with manifestations of chronic, low-grade anterior uveitis that may lead to cataract, glaucoma, vitreous opacities, and change of iris color. This condition is painless. All patients are seropositive for rubella, and intraocular antibody production of rubella (but not other pathogens) has been shown in adults and in a 13-year-old unvaccinated child [489,492].

## CONGENITAL INFECTION

Gregg's original report [12] in 1941 defined CRS as a constellation of defects, usually involving some combination of congenital heart, eye, and hearing abnormalities, with or without mental retardation and microcephaly. After the extensive studies in the mid-1960s, in which virologic and serologic methods of assessment were used, the pathologic potential associated with intrauterine rubella infection had to be greatly expanded [2,3]. The recognition of various new defects associated with congenital rubella infection led to speculation that they had not existed before the 1962–1964 pandemic. A review of the abnormalities in infants born during previous nonepidemic periods indicated, however, that they were not new, but had not been appreciated previously because of the small number of affected infants studied [493].

The virus can infect one or virtually all fetal organs and, when established, can persist for long periods (see "Transmission In Utero," "Natural History," "Pathogenesis," and "Pathology").* Congenital rubella, a chronic infection, may kill the fetus in utero, causing miscarriage or stillbirth. At the other extreme, the infection may have no apparent effect clinically detectable at the delivery of a normal-appearing infant. Alternatively, severe multiple birth defects may be obvious in the newborn period. The wide spectrum of disease is discussed later and summarized in Tables 28–3 and 28–4.

Silent infections in the infant are much more common than symptomatic ones. Schiff and colleagues [344] prospectively examined 4005 infants born after the 1964 rubella epidemic. Based on virologic and serologic techniques to detect infection in the newborns, the overall rate of congenital rubella was greater than 2% compared with only approximately 0.1% in endemic years [344,351]. Of the infected newborns, 68% had subclinical infection during the neonatal period. Among infants who were followed, 71% developed manifestations of infection at various times in the first 5 years of life. Many important rubella defects can be undetectable or overlooked in the early months of life. Existing manifestations of infection can progress, and new manifestations may appear throughout life.* Some abnormalities of CRS usually are not detected until the 2nd year of life or later (see Table 28–3). The silent and progressive nature of congenital rubella infection has important implications for accurate, timely diagnosis and appropriate short-term and long-term management.

It is useful to group the clinical features of congenital rubella into three categories: transient manifestations in newborns and infants; permanent manifestations, which may be present at birth or become apparent during the 1st year of life; and developmental and late-onset manifestations, which usually appear and progress during childhood, adolescence, and early adult life [13,452,494]. These groupings overlap.

## Transient Manifestations

Transient manifestations seem to reflect ongoing heavy viral infection, perhaps abetted by the newborn's emerging, often abnormal immune function [6,124,138]. Examples of these manifestations include hepatosplenomegaly, hepatitis, jaundice, thrombocytopenia with petechiae and purpura, discrete bluish red ("blueberry muffin") lesions of dermal erythropoiesis, hemolytic anemia, chronic rash, adenopathy, meningoencephalitis (in some cases), large anterior fontanelle, interstitial pneumonia, myositis, myocarditis, diarrhea, cloudy cornea, and disturbances in bone growth that appear as striated radiolucencies in the long bones. More than 50% of infants with these transient findings usually have evidence of intrauterine growth restriction and may continue to fail to thrive during infancy [289]. These transient abnormalities were referred to as the *expanded rubella syndrome* when widely reported after the pandemic of 1962–1964. Careful review of early observations during the 1940s and 1950s revealed that these were not new manifestations of congenital rubella.

These conditions usually are self-limiting and clear spontaneously over days or weeks [2]. These lesions are important from a diagnostic and prognostic standpoint.

They may be associated with other, more severe defects; this applies especially to thrombocytopenia and bone lesions [13,494]. The mortality rate was approximately 35% in one group of infants who presented with neonatal thrombocytopenia. Extreme prematurity, gross cardiac lesions or myocarditis with early heart failure, rapidly progressive hepatitis, extensive meningoencephalitis, and fulminant interstitial pneumonitis contributed to the mortality during infancy [452].

## Permanent Manifestations

Permanent manifestations include heart and other blood vessel defects, eye lesions, CNS abnormalities, deafness, and various other congenital anomalies. These structural defects result from defective organogenesis (i.e., some cardiac, eye, and other organ defects) and from tissue destruction and scarring (i.e., hearing loss, brain damage, cataracts, chorioretinopathy, and vascular stenosis). Relatively few defects result from gross anatomic abnormalities. It is uncertain that all of the malformations listed in Table 28–5 are associated with congenital rubella [13,325,391,465,493–521]. Because many of them occur in the absence of intrauterine rubella infection, their presence in affected infants may be coincidental [9].

Congenital heart disease is present in more than half of children infected during the first 2 months of gestation. The most common lesions, in descending order, are patent ductus arteriosus, pulmonary artery stenosis, and pulmonary valvular stenosis. Aortic valvular stenosis and tetralogy of Fallot have also been recorded. A patent ductus arteriosus occurs alone in approximately one third of cases; otherwise, it is frequently associated with pulmonary artery or valvular stenosis [13,494,506]. Stenosis of other vessels plays an important role in the spectrum of CRS [456,515,516]. These lesions may be related to coronary, cerebral, renal, and peripheral vascular disease seen in adults [135,522].

*Frequency of occurrence is classified as follows: +, <20%; ++, 20%–50%; +++, 50%–75%.*
[†]*Rarely associated with rubella syndrome (whether caused by infection is unknown). Incidence is seemingly increased in infants with congenital rubella.*

A "salt and pepper" retinopathy caused by disturbed growth of the pigmentary layer of the retina is the most common ocular finding [6,13,452,494]. Cataracts, often accompanied by microphthalmia, occur in approximately one third of all cases of congenital rubella. Bilateral cataracts are found in half of affected children. Primary glaucoma is uncommon; it does not affect a cataractous eye. Cataracts and infantile glaucoma may not be present or detectable at birth, but usually become apparent during the early weeks of life. Other ocular abnormalities occur later in life (see "Developmental and Late-Onset Manifestations").

Children with CRS exhibit numerous CNS abnormalities that follow widespread insult to the brain. Microcephaly can be a feature of this syndrome. Mental retardation and motor retardation are common and are directly related to the acute meningoencephalitis in 10% to 20% of affected children at birth [9]. Behavioral and psychiatric disorders have been confirmed in many patients [13,452].

Of particular interest is autism, which has been reported to occur with a frequency of approximately 6% [452]. Chronic encephalitis has been reported in young children [6]. Late-onset progressive panencephalitis may occur in the 2nd decade of life [398,483,484]. This condition is discussed later with other developmental manifestations.

The incidence of deafness has been underestimated because many cases had been missed in infancy and early childhood. Follow-up studies showed that deafness was the most common manifestation of congenital rubella, however, occurring in 80% or more of children infected.* In contrast to other serious defects, hearing impairment often is the only significant consequence of congenital rubella. Rubella-related defects of organogenesis (i.e., cataracts and some heart lesions) are uncommon after infection beyond 8 weeks of gestation. The organ of Corti is vulnerable to the effects of the virus up to the first 16 weeks, however, and perhaps up to the first 18 to 20 weeks. Deafness, ranging from mild to profound and from unilateral or bilateral, is usually peripheral (sensorineural) and is more commonly bilateral. Central auditory impairment and language delay may lead to a misdiagnosis of mental retardation [13,523–527].

## Developmental and Late-Onset Manifestations

Developmental and late-onset manifestations have been reviewed by Sever and Shaver and their colleagues [135,136]. These manifestations include endocrinopathies, deafness, ocular damage, vascular effects, and progression of CNS disease (see Table 28–3).† Numerous mechanisms may be responsible for the continuing disease process that leads to these abnormalities, including persistent viral infection, viral reactivation, vascular insufficiency, and immunologic insult. The last problem may be mediated by circulating immune complexes and autoantibodies. Hyper-IgM syndrome with combined immunodeficiency and autoimmunity has been reported [528]. Abnormalities in cellular immunity and genetic factors have also been studied.

Insulin-dependent diabetes mellitus is the most frequent of all these manifestations, occurring in approximately 20% of patients by adulthood [13,121,129, 134–136,529]. This reported prevalence is 100 to 200 times that observed for the general population. A Japanese study of CRS patients with 40 years of follow-up reported only 1.1% diabetics, however [529a]. Studies of HLA type indicate that CRS patients with diabetes have the same frequencies of selected HLA haplotypes as diabetic patients without CRS (e.g., increased HLA-DR3 and decreased HLA-DR2). The presence of pancreatic islet cell and cytotoxic surface antibodies in children with CRS does not seem to be related to any specific HLA type. It has been postulated that congenital infection increases the penetrance of a preexisting susceptibility to diabetes in these patients [134]. Rabinowe and coworkers [137] also reported an elevation in the number of Ia-positive ("activated") T cells in patients with CRS. They suggested that this T-cell abnormality may be related in these patients to the increased incidence of diabetes mellitus and other diseases associated with autoantibodies.

Thyroid dysfunction affects about 5% of patients and manifests as hyperthyroidism, hypothyroidism, and thyroiditis [121,133,530–535]. Autoimmune mechanisms seem to be responsible for these abnormalities. Clarke and colleagues [133] reported that 23% of 201 deaf teenagers with congenital infection had autoantibodies to the microsomal or globulin fraction, or both fractions, of the thyroid and that 20% of those with autoantibodies had thyroid gland dysfunction. Coexistence of diabetes and thyroid dysfunction has been reported, but the significance of the association is unknown [121,137].

Two cases of growth hormone deficiency have been reported [536]. The defect seems to be hypothalamic in origin. Among eight growth-restricted older children with CRS, Oberfield and associates [537] found no evidence, however, of functional abnormality in the hypothalamic-pituitary axis and normal or elevated levels of somatomedin C. Growth patterns in 105 subjects in late adolescence revealed three patterns: growth consistently below the fifth percentile; growth in the normal range, but early cessation of growth, usually with a final height below the fifth percentile; and normal growth. The magnitude of the cognitive deficits was closely correlated with growth failure [538]. Ziring [14] commented on a case with Addison disease, and precocious puberty has been observed [13,14].

The delayed diagnosis of preexisting deafness has already been mentioned. The hearing deficit can increase over time, however, and sudden onset of sensorineural deafness may occur after years of normal auditory acuity [356,539,540]. As reported by Sever and coworkers [135], the latter has been observed in a 10-year-old child.

Many late-onset ocular defects can occur. Glaucoma has been reported in patients 3 to 22 years old who did not previously have the congenital or infantile variety of glaucoma associated with CRS [541]. Other reported manifestations are keratic precipitates, keratoconus, corneal hydrops, and spontaneous lens absorption [542].

The retinopathy of congenital rubella, which was previously believed to be completely benign, has more recently been associated with the delayed occurrence of visual difficulties caused by subretinal neovascularization [543–545]. Another delayed manifestation associated with vascular changes is hypertension resulting from renal artery and aortic stenosis [522].

Mental retardation, autism, and other behavioral problems may be delayed in appearance and can be progressive [13,452]. The most serious delayed CNS manifestation is the occurrence of a progressive and fatal panencephalitis resembling subacute sclerosing panencephalitis, which manifests during the 2nd decade of life. The first cases were reported by Weil and Townsend and their coworkers [398,483]. At the time of their review, Waxham and Wolinsky [484] found that 10 cases of progressive rubella panencephalitis had been identified among patients with CRS. Two cases have been reported after postnatally acquired rubella [445,446]. Patients with this condition present with increasing loss of mental function, seizures, and ataxia. These symptoms continue to progress until the patient is in a vegetative state and ultimately dies.

*References 6, 9, 13, 14, 111, 135, 136, 340, 341, 343–346.

†References 13, 14, 121, 129, 134, 135, 137, 340, 345, 411, 484, 485, 503, 516, 522–527, 529–537, 540–546, 616, 617.

Rubella virus has been recovered from the brain of one congenitally infected patient [398]. Elevated serum and cerebrospinal fluid antibodies and increased amounts of cerebrospinal fluid protein and γ-globulin have been detected. Virus has also been isolated from lymphocytes, and rubella-specific immune complexes have been identified [125,546]. Although rare, this syndrome focuses attention on the ability of the virus to persist and to become reactivated after years of latency.

### Long-Term Prognosis

Investigators examined 50 survivors of the congenital rubella epidemic of 1939–1943 in Australia at age 25, and their status was reviewed again in 1991 [547]. Seven subjects had died in the interval—three with malignancies, three with cardiovascular disease, and one with acquired immunodeficiency syndrome (AIDS). Among the survivors in 1991, 5 were diabetic, all 40 examined were deaf, 23 had eye defects, and 16 had cardiovascular defects. Despite these conditions, the group was characterized by remarkably good social adjustment. Most (29) were married, and they had 51 children—only 1 with a congenital defect (deafness presumed to be hereditary from his deaf father, who did not have congenital rubella). Most survivors were of normal stature, although 6 of the 40 were less than the third percentile for height.

The group of survivors from Australia is quite different from the approximately 300 survivors followed in New York since the rubella epidemic of 1963–1965 [39]. In their late 20s, approximately one third of these survivors were leading relatively normal lives in the community, one third were living with their parents with "noncompetitive" employment, and one third were residing in facilities with 24-hour care. Neither the Australian nor the New York group is a representative sample of all survivors of maternal rubella infection, but these groups do offer insight on long-term prognosis. The differences in outcome between the Australian group (survivors of Gregg's original patients) and the New York group probably reflect the different methods by which the groups were collected and the significant differences in the medical technology of the 1940s compared with the 1960s.

## LABORATORY DIAGNOSIS

Timely, accurate diagnosis of acute primary rubella infection in a pregnant woman and congenital rubella infection in an infant is imperative if appropriate management is to be undertaken (see "Management Issues"). The diagnosis must be confirmed serologically or virologically because clinical diagnosis of postnatal and congenital rubella is unreliable. In any suspected exposure of a pregnant woman, every effort should be made to confirm rubella infection so that accurate counseling can be offered about the risks to the fetus. Laboratory proof of congenital infection facilitates proper treatment, follow-up, and long-term management.

### MATERNAL INFECTION

All women of childbearing age should have been vaccinated against rubella as children or in gynecologic care before conception. In addition, they should be screened for rubella IgG antibodies at the first obstetric visit and tested further for IgM antibodies (see later) if they give a history of rash or exposure to rash illness earlier in pregnancy. Most experts accept an enzyme-linked immunosorbent assay titer of 10 IU or greater as an indication of immunity; however, some experts accept greater than 15 IU [548,549]. Women who are IgG antibody negative at the first visit should be retested 2 to 3 weeks later if the fetus is less than 16 weeks' gestational age to exclude intercurrent infection. All seronegative women should be vaccinated postpartum [550].

Because of inapparent infection, the variable clinical manifestations of rubella, and the mimicking of rubella by other viral exanthems, laboratory diagnosis is essential in managing potential rubella infection during pregnancy (see "Natural History" and "Clinical Manifestations") [161,210,237,238,551]. Although virus can be cultured from the nose and throat, isolation techniques are slow and labor-intensive. Reverse transcriptase PCR offers another reliable tool for confirming the diagnosis during acute rubella, but laboratory confirmation of acquired infection in nonpregnant persons is usually limited to serologic testing (see "Virus").

Acute primary infection can usually be documented by showing a significant increase in rubella IgG antibody level between acute and convalescent sera or the presence of rubella-specific IgM antibody. Appropriate timing of specimen collection with regard to rash onset (or exposure in the case of subclinical infection) is crucial for accurate interpretation of results. Diagnosis is greatly facilitated if the immune status is known before disease onset or exposure [270]. Women with laboratory evidence of immunity are not considered to be at risk. From a practical point of view, women with a history of vaccination on or after the first birthday should also be considered immune [267,268]. Because seroconversion is not 100% (see "Prevention of Congenital Rubella"), serologic testing may be indicated on an individual basis in vaccinated women who have a known exposure or a rash and illness consistent with rubella to rule out acute primary infection or reinfection.

Traditionally, a fourfold or greater increase in antibody titer (i.e., HI, complement fixation, or latex agglutination tests) has been considered a significant increase in antibody. With the advent of enzyme immunoassay, the diagnosis may be based on significant changes in optical density expressed as an index rather than a titer. The acute phase specimen should be obtained as soon as possible after onset of the rash, ideally within 7 days. If a positive titer is obtained for a specimen taken on the day of rash onset or 1 to 2 days later, the risk of acute infection is low, but cannot be excluded. The convalescent phase serum sample should be taken 10 to 14 days later. If the first serum sample is obtained more than 7 days after rash onset, some assays (e.g., HI) may be unable to detect a significant antibody increase because titers may have already peaked. In this situation, measurement of antibodies that appear later in the course of infection may be useful. A significant increase in complement fixation titer or a high HI, latex agglutination, or enzyme immunoassay titer and little or no antibody as measured by passive hemagglutination suggests recent infection.

When multiple serum samples are obtained in the course of the diagnostic work-up, all should be tested simultaneously in the same laboratory to avoid misinterpretation of laboratory-related variations in titer. Although a single high titer is consistent with recent infection, it is not specific enough to conclude that recent infection has occurred [270].

Detection of rubella-specific IgM is a very useful method for confirming acute recent infection. Although rubella-specific IgM testing is valuable, numerous factors can affect test results. Results must be interpreted with careful attention to the timing of the specimens. Samples obtained within the first several days after onset of rash may have low or undetectable levels of rubella-specific IgM, but a specimen obtained 7 to 14 days later invariably shows higher titers of antibody. The levels of rubella-specific IgM may decline promptly thereafter. Many of the methods previously described for detecting IgM have some limitations (see "Virus"). IgM antibody testing may involve pretreatment of the serum by various techniques to separate IgM from IgG, such as column chromatography, sucrose gradient centrifugation, or adsorption of IgG with staphylococcal protein A.

The serum IgM fraction can be assayed by HI, immunofluorescence, radioimmunoassay, or enzyme immunoassay.* A false-positive result may occur if the serum was pretreated with protein A because about 5% of IgG is not removed. The radioimmunoassay and enzyme immunoassay techniques can detect specific IgM antibodies directly in unfractionated sera, but false-positive results may be produced by the presence of rheumatoid factor [161,218,220]. A solid-phase, immunosorbent (i.e., capture) technique seems to be unaffected by rheumatoid factor [103,221,236,247]. A warning is necessary.

Although high or moderate titers provide very good evidence of recent infection, low rubella-specific IgM titers detected by sensitive assays must be interpreted cautiously. Low titers have been shown to persist for many months in a few patients after natural infection and can be detected in some immune patients with subclinical reinfection [45,55,57,59,365–370]. Diagnosis of subclinical infection is straightforward if the woman is known to be susceptible, the exposure is recognized, and a serum sample is obtained approximately 28 days after exposure.

The diagnosis of subclinical infection is more difficult if the immune status of the woman is unknown. It can be facilitated, however, if the acute-phase serum specimen is obtained as soon as possible after a recognized exposure that did not occur more than 5 weeks earlier [270]. The convalescent serum sample, if necessary, should be obtained approximately 3 weeks later. If the first specimen lacks detectable antibody, continued close clinical observance and serologic follow-up are necessary. If the first specimen has detectable antibody and was obtained within 7 to 10 days of exposure, there is no risk of infection, and further evaluation is unnecessary. A positive titer in a specimen obtained after this period indicates a need for further serologic investigation. If test results of paired serum specimens are inconclusive, rubella-specific IgM testing may be helpful, but a negative test result may be difficult to interpret. Dried blood spots have been useful in the detection of IgM antibodies because they show concordance with serum determinations [552,553].

More significant diagnostic difficulties arise when women of unknown immune status are exposed at an unknown time, were exposed more than 5 weeks earlier, or had rash onset more than 3 weeks earlier [270]. In these situations, expert consultation may be necessary if positive titers are obtained. Where available, avidity testing of rubella IgG may be used to help clarify the timing of infection. Recent rubella infection is characterized by antibody of low avidity. When such low-avidity antibody is found in the presence of rubella-specific IgM, it supports a diagnosis of recent rubella infection [368–370]. Avidity results, which relate to the binding of antibody to the E1 protein, can be crucial in distinguishing recent from past infection [554,555].

Table 28–6 gives information on the prevalence of IgM antibodies and positive reverse transcriptase PCR results in acquired infection according to time since onset of rash [556]. Figure 28–8 shows the pattern of test results according to the stage of infection [25].

Conclusive information about the timing of past infection and risk to the fetus is often unavailable, even when a combination of antibody assays is used. These situations

can be minimized if prenatal rubella testing is done routinely. Laboratories performing prenatal screening should store these specimens until delivery in case retesting is necessary [267,551].

## CONGENITAL INFECTION

A presumptive diagnosis of congenital rubella infection should be considered for any infant born to a mother who had documented or suspected rubella infection at any time during pregnancy (see "Transmission In Utero") [107,113]. The diagnosis should also be considered in any infant with evidence of intrauterine growth restriction and other stigmata consistent with congenital infection, regardless of maternal history (see "Clinical Manifestations"). Although such findings are sensitive for clinically apparent disease, they are nonspecific because many of them can be associated with other intrauterine infections, such as cytomegalovirus infection, syphilis, and toxoplasmosis. Many affected infants are asymptomatic. As with maternal rubella, congenital infection must be confirmed by laboratory tests.

In contrast to maternal rubella, attempting to isolate rubella virus in tissue culture is a valuable tool for diagnosing congenital rubella in newborns. The virus is most readily isolated from the posterior pharynx and less consistently from the conjunctivae, cerebrospinal fluid, or urine.* Virus isolation should be attempted as soon as congenital rubella is suspected clinically because viral excretion wanes during infancy (see Fig. 28–7). In older children in whom virus shedding has ceased from other sites, virus may be isolated from cataractous lens tissue [395]. In children with encephalitis, virus may persist in the cerebrospinal fluid for several years [370–372,503].

There are two approaches for serologic diagnosis. First, cord serum can be assayed for the presence of rubella-specific IgM antibody [399,401,410,411]. Detectable IgM antibody is a reliable indicator of congenital infection because IgM is fetally derived. False-positive results may occur, however, because of rheumatoid factor or incomplete removal of IgG (largely maternal), depending on the techniques used. A few newborns with stigmata of congenital rubella may not have detectable levels of rubella-specific IgM in sera taken during the first days of life, and some infections may go undiagnosed if infection occurred late in pregnancy because it is theoretically possible that there was inadequate time for the fetus to produce detectable levels of specific IgM antibodies by the time of delivery [13,107,113].

A second approach is to monitor IgG levels in the infant over time to see if they persist. Maternally derived antibodies have a half-life of approximately 30 days [399,401,411]. As measured by the HI test, they usually decline at a rate of one twofold dilution per month and would be expected to disappear by 6 to 12 months of age (see Fig. 28–5). Persistence of IgG antibody at this age, especially in high titer, is presumptive evidence of intrauterine infection with rubella virus. Sera should be

*References 2, 13, 165, 288–293, 295, 324, 325, 327, 329, 393, 396.

drawn when the infant is 3 months and 5 to 6 months old, with a repeat specimen at 12 months if necessary. All serum samples should be tested in parallel.

Important limitations of this method are the delay in diagnosis and the fact that rubella infections occurring after birth may be mistaken for congenital infections [107,557]. The latter is usually more of a problem when attempting to diagnose congenital infection retrospectively in patients beyond infancy, especially if the incidence of rubella in childhood is high or vaccine has already been administered. A third limitation is that some infants and children with CRS (particularly older children) may lack antibody as measured by HI [345, 413–415]. If the diagnosis is still suspected, and the HI, IgM, and culture results are negative, retesting with an assay that detects antibody to all components of the virion, such as some enzyme immunoassays, is advised [91]. Some cases with undetectable HI antibody may be from an incomplete immune response to all the structural proteins of the virus, including the hemagglutinin (see "Virus") [86,87].

Other diagnostic methods, such as measurement of cellular immunity and response to vaccine (i.e., a failure to boost antibody titer), may also be helpful in this situation, but a definitive retrospective diagnosis often cannot be made [382,431,558,559]. Cerebrospinal fluid may also be examined for the presence of rubella-specific IgM [560]. As in the case for acquired infection, determination of avidity of IgG may be useful [368,370,561].

The availability of sensitive and specific tests for prenatal diagnosis of fetal infection after suspected or documented maternal rubella can greatly facilitate counseling. Although positive diagnoses were reported from examination of amniotic fluid, fetal blood, and chorionic villus sampling for virus isolation, rubella-specific IgM and antigens, interferon, and RNA [103,438,562–568], the low sensitivity of these assays added little to the counseling process. Reverse transcriptase nested PCR has been reported to offer a far more reliable and rapid tool and, where available, a valuable aid to counseling [189,569,570]. Timing of the specimen collection related to the timing of maternal infection may influence sensitivity, which reached 100% (eight of eight specimens) for amniotic fluid in one study and 83% (five of six specimens) for chorionic villus sampling in another study. Repeat testing may increase the yield of positive specimens [189,562].

Postnatal diagnosis of congenital rubella infection is based on one or more of the following tests: isolation of virus or positive reverse transcriptase PCR from fetal tissues or postnatal respiratory secretions, the demonstration of rubella-specific IgM antibodies in cord blood or neonatal serum, and persistence of rubella IgG antibodies beyond the 3 to 6 months required for elimination of maternally transmitted antibodies [187]. Figure 28–9 is an algorithm for diagnosis of maternal and congenital rubella proposed by Mendelson and colleagues [187].

## MANAGEMENT ISSUES

The major management issues associated with postnatal infection arise when a pregnant woman is at risk of acquiring infection. Confirming the diagnosis, counseling about the risks of infection of and damage to the fetus, and discussing courses of action including the use of immunoglobulin and consideration of termination of pregnancy require a thorough understanding of the natural history and consequences of rubella in pregnancy. In the case of congenital infection, the emphasis is on diagnosis and acute and long-term management. Isolation may be important to reduce spread of infection.

### USE OF IMMUNOGLOBULIN

The role of passive immunization with immunoglobulin after exposure to rubella is controversial.* Brody and coworkers [572] reported that large doses of immunoglobulin may have some efficacy, but immunoglobulin generally proved to be more useful when given prophylactically than when administered after exposure. This finding is not surprising because extensive viral replication is demonstrable 1 week or more before symptoms appear, with initial replication probably beginning even earlier. The amount of antirubella antibody in commercial immunoglobulin preparations is variable and unpredictable; specific hyperimmunoglobulin preparations are unavailable [574,575].

Theoretically, the role of circulating antibodies in rubella is mainly to limit the viremia and possibly to prevent replication at the portal of entry; antibody is less valuable after infection has begun. Fetal infection occurred when immunoglobulin was administered to the mother in what seemed to be adequate amounts soon after exposure. Another disadvantage of immunoglobulin is that it may eliminate or reduce clinical findings without affecting viral replication. Clinical clues of maternal infection would be masked without adequate protection of the fetus, resulting in a false sense of security.

It is recommended that use of immunoglobulin be confined to rubella-susceptible women known to have been exposed who do not wish to interrupt their pregnancy under any circumstances [266,268]. In this situation, large doses (20 mL in adults) should be administered. The patient should be advised that protection from fetal infection cannot be guaranteed.

### TERMINATION OF PREGNANCY

A discussion of the complex issues involved in the decision about termination of pregnancy for maternal rubella is beyond the scope of this chapter. The decision must be carefully weighed by the physician and the prospective parents. The physician must have a thorough understanding of the known facts about the pathogenesis and diagnosis of congenital rubella and the risks to the fetus depending on the timing of maternal infection. Where available, analysis of amniotic fluid, fetal blood, or chorionic villus sampling by reverse transcriptase nested PCR may assist in antenatal diagnosis of infection [189, 569,570]. Expert consultation is desirable to ensure that the most current information is used in the decision-making process.

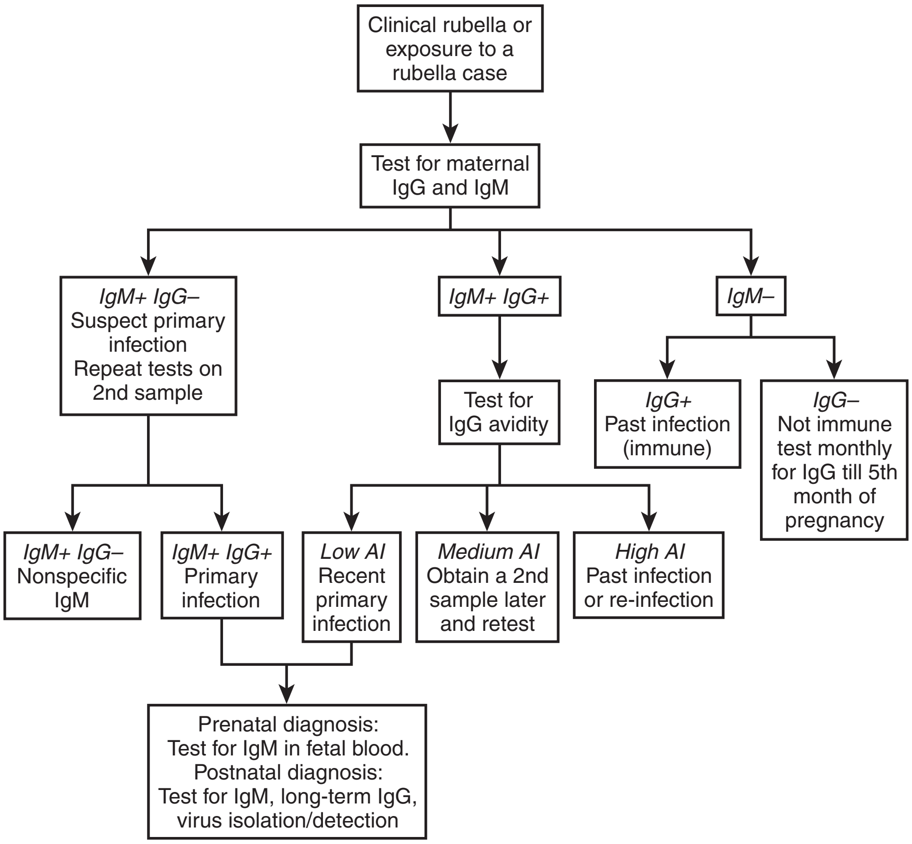

**FIGURE 28–9 Algorithm for assessment of rubella infection in pregnancy shows a stepwise procedure beginning with testing of maternal blood for IgM and IgG.** If maternal blood is negative for IgM (IgM−), the IgG results determine if the woman is seropositive (immune) or seronegative (not immune). If not immune, the woman should be retested monthly for seroconversion until the end of the 5th month of pregnancy. If the maternal blood is positive for IgM (IgM+) and IgG (IgG+), the next step would be an IgG avidity assay on the same blood sample to estimate the time of infection. Low avidity index (AI) indicates recent infection, whereas high AI indicates past positive and IgG negative (IgG−); recent primary infection is suspected, and the same tests should be repeated on a second blood sample obtained 2 to 3 weeks later. If the results remain the same (IgM+ IgG−), the IgM result is considered nonspecific, indicating that the woman has not been infected (however, she is seronegative and should be followed until the end of the 5th month). If the woman has seroconverted (IgM+ IgG+), recent primary infection is confirmed, and a prenatal diagnosis should be made if the woman wishes to continue her pregnancy. Determination of IgM in cord blood is the preferred diagnostic method with the highest prognostic value. Postnatal diagnosis is based on the newborn's serology (IgM for 6 to 12 months and IgG for >6 months) and on virus isolation from the newborn's respiratory secretions. *(Adapted from Mendelson E, et al. Laboratory assessment and diagnosis of congenital viral infections: rubella, cytomegalovirus [CMV], varicella-zoster virus [VZV], herpes simplex virus [HSV], parvovirus B19 and human immunodeficiency virus [HIV]. Reprod Toxicol 21:350-382, 2006.)*

## CLINICAL MANAGEMENT

Acute rubella infection usually requires little clinical management. A patient with congenital infection may require medical, surgical, educational, and rehabilitative management, however. Many lesions are not apparent at birth because they have not yet appeared or cannot be detected. In keeping with its chronicity, congenital rubella must be managed as a dynamic rather than a static disease state. A continuing effort on the part of the physician must be made to define initially the extent of the problem and to detect evidence of progressive disease or emergence of new problems over time. Because of the broad range of problems, a multidisciplinary team approach to care is essential.

Complete pediatric, neurologic, cardiac, ophthalmologic, and audiologic examinations should be complemented by complete blood cell count, radiologic bone surveys, and often evaluation of cerebrospinal fluid for all newborns in whom the diagnosis is suspected, whether the infant is symptomatic or not. Some defects, such as interstitial pneumonitis, can be slowly progressive and apparently cause major functional difficulties months after birth. Infected infants require scrutiny during the first 6 months of life. Serial assessment for immunologic dyscrasias is necessary during this period because the humoral defects may be masked by the presence of maternal immunoglobulin.

Hearing defects and psychomotor difficulties are the most important problems because of their high incidence. Both often occur in infants who are initially asymptomatic. The new techniques for detection of hearing impairment in newborns and the state-mandated universal newborn hearing screening testing requirements have been initiated too recently to determine their utility in detection of unsuspected congenital rubella. Delay in diagnosis and therapeutic intervention has a profound impact on language development and skills acquisition and can magnify psychosocial adjustment problems within the entire family constellation.

Because many children with congenital rubella have multiple handicaps, early interdisciplinary treatment is warranted. Appropriate hearing aids; visual aids, including contact lenses; speech, language, occupational, and physical therapy; and special educational programs are frequently required for such children. Serial psychological and perceptual testing may be very helpful for ongoing management, particularly when performed by individuals experienced in assessing children with multiple handicaps who are sensorially deprived. In many cases, repeated testing is important because the problems seem to be progressive and require continuing assessment of the therapeutic approach. In the United States, most infants suspected to have congenital rubella are eligible for early intervention and habilitation services authorized by the Individuals with Disabilities Education Act. These programs offer services to affected children beginning in infancy, a critical time for children who may be hearing impaired. The impact of universal newborn hearing screening programs as another tool for early detection of congenital rubella and of cochlear implants for children with severe rubella deafness remains to be determined.

## CHEMOTHERAPY

Because postnatal rubella is usually mild, there has been little need to pursue chemotherapeutic regimens, and the literature on this subject is sparse. Interferon has been used to treat chronic arthritis, and inosine pranobex (Isoprinosine) has been administered to a patient with postnatally acquired progressive rubella panencephalitis [446,546,576]. Chance temporal association between interferon administration and reported improvement in joint symptoms cannot be differentiated from potential therapeutic benefits of the interferon. In the trial of inosine pranobex, no improvement was observed.

Reports regarding treatment of infants with congenital rubella are limited. The course of congenital infection does not seem to be altered by any available chemotherapeutic agent. Because amantadine reduces the replication of rubella virus in vitro, it has theoretical possibilities as a chemotherapeutic agent [162–164]. Its use has been confined, however, to a 5-month-old infant with congenital infection [165]. Neither virus excretion nor clinical status was affected. Interferon has also been administered to a few infants with CRS. Arvin and associates [577] reported that nasopharyngeal excretion in three infants (3 to 5 months old) persisted throughout interferon administration, although at reduced titers compared with baseline. There was, however, no clinical effect. Larsson and coworkers [578] administered interferon to a 14-month-old child and reported regression of a cutaneous eruption resulting from vasculitis and disappearance of viremia. Viruria and other signs of viral persistence (e.g., rubella-specific IgM in the cerebrospinal fluid) were unaffected. It is also uncertain whether improvement in the rash was from interferon administration or was coincidental. A 10-month-old infant treated by Verder and coworkers [138] may have benefited from interferon, but improvement was also seen after exchange transfusions that preceded the interferon treatment. Inosine pranobex has been administered to some patients with progressive rubella panencephalitis [546,579]. As for postnatally acquired disease, the results in this case have been disappointing.

## ISOLATION

Patients with rubella are considered infectious from the 7th day before to the 5th to 7th day after the onset of the rash and should be placed in contact isolation [580,581]. Exposed rubella-susceptible patients confined to the hospital should be placed in contact isolation from the 7th through 21st day after exposure and tested appropriately to rule out asymptomatic infection [582]. Infectious patients with congenital rubella should also be in contact isolation [580]. Isolation precautions should be instituted as soon as rubella or congenital rubella is suspected. Only persons known to be immune (i.e., persons with serologic evidence of immunity or documentation of vaccination on or after the 1st birthday) should care for infectious or potentially infectious patients [266,268].

Children with CRS should be considered infectious for the 1st year of life unless repeated pharyngeal and urine culture results are negative [268,580]. Culture results are unlikely to become negative until the child is 3 to 6 months old (see Fig. 28–4). From a practical point of view, children older than 1 year are unlikely to be a significant source of infection. In the home situation, susceptible pregnant visitors should be informed of the potential risk of exposure.

# PREVENTION OF CONGENITAL RUBELLA

## RUBELLA VACCINE AND IMMUNIZATION STRATEGIES

Active immunization is the only practical means to prevent congenital rubella because passive immunization provides unreliable, transient protection (see “Management Issues”). There has been considerable debate, however, about the best way to use the vaccine [3,5–7,32,37,583]. Because rubella vaccination is not aimed primarily at protecting the individual, but rather the unborn fetus, two basic strategies have been proposed: universal childhood immunization and selective vaccination of susceptible girls and women of childbearing age. The former approach is designed to interrupt transmission of virus by vaccinating the reservoir of infection; reduce the overall risk of infection in the general population; and provide indirect protection of unvaccinated, postpubertal women. The latter approach directly protects women at risk of being infected when pregnant, limits overall vaccine use, and allows virus to circulate and boost vaccine-induced immunity in the population. Experience gained during the past 30 years indicates that integration of both approaches is necessary to achieve maximum control in the shortest possible time [5,32,35,37].

At the time of licensure in 1969, available information indicated that the live-attenuated rubella vaccines were safe, noncommunicable, and highly effective [3,4,27–29]. Although information on the duration of vaccine-induced immunity was limited, public health policy makers in the

United States believed that vaccination of all children would provide protection into the childbearing years. The duration and quality of the immunity would have to be monitored continually. Because vaccine virus could cross the placenta and infect the fetus, cautious recommendations for vaccination of susceptible women of childbearing age were also proposed [343,584,585]. Vaccine was to be administered in this population only after susceptibility had been documented by serologic testing. Vaccinated women were also advised to avoid conception for 2 months after vaccination. After Fleet and colleagues [586] isolated virus from the fetus of a woman who had conceived 7 weeks before vaccination, this time interval was increased to 3 months as an extra precaution [266,268].

In some areas of the world, mass vaccination was considered undesirable because of concerns about the duration of vaccine-induced immunity [5–7,34,111]. Instead, vaccine was targeted for all girls 11 to 14 years of age and postpubertal women known to be seronegative. As with the U.S. program, pregnancy was to be avoided for 3 months after immunization. The goal was to immunize at least 90% of the women immediately at risk and simultaneously to provide a higher level of immunity throughout the group of women of childbearing age. It was recognized that this approach would take many years to have a significant effect on the incidence of congenital infection.

The U.S. strategy prevented epidemic disease, but initially had little effect on the occurrence of infection in young adults, particularly women of childbearing age (see "Epidemiology").* There was no evidence that infection was occurring in individuals who had been vaccinated years earlier (see "Update on Vaccine Characteristics"). Childhood vaccination decreased the overall risk of infection, but virus could still circulate in the community, especially wherever unvaccinated adolescents and adults congregated [271–279,282–287]. Although CRS could eventually be eliminated as vaccinated cohorts of children entered the childbearing years, this process would take many years, and potentially preventable cases of congenital infection would continue to occur [279]. Specific recommendations were made to increase vaccination levels in older individuals, particularly women of childbearing age (see "Vaccination Recommendations") [266,268].

Selective vaccination programs have not been successful because of the inability to immunize a sufficient proportion of the female population [7,35,36]. With this immunization approach, large-scale epidemics continue to occur, and the incidence of congenital rubella has not declined significantly since the introduction of vaccines. Because of these problems, in 1988, Great Britain implemented a program of MMR vaccination for all children in the 2nd year of life and initial catch-up in 2- to 4-year-olds. In 1994, a mass measles-rubella vaccine program for 5- to 16-year-old recipients was conducted to avert a measles epidemic. A preschool MMR booster was added in 1996 [35,37,587].

*References 5, 24, 33, 39, 269, 303.

As highlighted in the previous paragraphs, the U.S. and UK programs adopted a combined approach to rubella control and elimination by the universal vaccination of children and selective vaccination of women of childbearing age. In 1997, as part of a regional initiative for rubella control and CRS prevention, PAHO developed a rubella and CRS control strategy that included introduction of a rubella-containing vaccine into routine childhood immunization programs, ensuring rubella vaccination of women of childbearing age to reduce the number of susceptible infants and to develop specific vaccination strategies for accelerated rubella control and CRS prevention. Two strategies for accelerated rubella control and CRS prevention were provided: Countries wishing to prevent and control CRS promptly were advised to conduct a one-time mass campaign to vaccinate all females 5 to 39 years of age with measles and rubella–containing vaccine, and countries wishing to prevent and control rubella and CRS promptly were advised to carry out a one-time mass campaign to vaccinate males and females 5 to 39 years of age with measles and rubella–containing vaccine [588].

## Update on Vaccine Characteristics

Approximately 200 million doses of vaccine have been administered in the United States since rubella vaccines were licensed in 1969. The RA 27/3 strain of vaccine was licensed for use in Europe in 1971 and in the United States in 1979 and is now the only vaccine available. It was attenuated by serial passage in the WI-38 fetal human diploid cell strain with adaptation to growth at 30° C and is manufactured in the MRC-5 human diploid cell strain [387,586,589]. Although it has been used successfully by the intranasal and aerosol routes [590,591], it is licensed only for subcutaneous administration, usually as part of a combination with measles and mumps vaccines [592]. Compared with the Cendehill or HPV-77 strains of vaccines, the RA 27/3 vaccine elicits an immune response that more closely resembles the response occurring after natural infection [31,203,386,387]. There are no data to indicate the need for revaccination of persons who had previously received vaccine strains other than the RA 27/3.

Appropriate administration of the RA 27/3 vaccine induces an antibody response in 95% or more of persons 12 months old or older when vaccinated. Antibody is induced to the three major rubella virus structural proteins [86]. Vaccine efficacy and challenge studies indicate that more than 90% to 95% of vaccinated persons are protected against clinical illness or asymptomatic viremia. Although vaccine-induced titers are lower than titers after natural infection and are more likely to increase after reexposure, protection after a single dose of vaccine lasts for at least 18 years, if not for life.*

Detectable HI antibodies persist in almost all vaccinated subjects who initially seroconvert.† In current practice, most children receive two doses of a rubella-containing

*References 42–44, 47, 48, 50, 52–54, 58, 60, 61, 271, 316, 603–606.

†References 43, 47, 50, 52, 58, 61, 322, 593–598.

vaccine, however, which does seem to improve seropositivity [599,600]. A survey of U.S. military recruits showed that 93% were seropositive for rubella [601]. Long-term studies of vaccinated persons who initially seroconverted and then lost detectable HI antibodies indicate that most of these individuals are also immune because they have detectable antibodies as measured by other, more sensitive assays or have a booster immune response (i.e., absence of IgM antibody and a rapid increase and decrease in IgG antibody) after revaccination [47,53,602].

Viremia and reinfection have been documented in some vaccinated persons and some naturally immune individuals who had very low titers of antibody [42,44,48,54,60]. It is unknown how often this phenomenon occurs or places the fetus at risk, but the incidence of both events is believed to be low [8]. There are rare case reports of congenital infection after reinfection of mothers who had been previously infected or vaccinated (see "Virus" and "Natural History").* The lack of an international standard level of antibody considered to be protective frequently complicates the interpretation of serologic data when antibodies are detected only by tests more sensitive than the HI test. Cutoff levels ranging from 5 to 15 IU have been used.† Available information indicates that any appropriately measured level of detectable antibody should be considered presumptive evidence of past infection and immunity [266,268]. This applies to naturally acquired and vaccine-induced immunity.

Rubella vaccine is remarkably safe. Rash, low-grade fever, and lymphadenopathy are occasionally observed. The polyneuropathies, myositis, and vasculitis associated with the HPV-77 strain of vaccine have not been reported after administration of the RA 27/3 strain [9,604].

Vaccine-related arthralgia and arthritis remain a concern, particularly for susceptible women.‡ Although arthralgia has been reported in 3% of susceptible children, arthritis has been reported rarely in these vaccinated subjects. In contrast, joint pain occurs in 40% of susceptible vaccinated women, with arthritis-like signs and symptoms reported in 10% to 20% [5,68]. Persistent and recurring joint complaints have been reported, but most studies indicate that they occur infrequently. The high frequency (5%) of persistent joint symptoms reported by one group of investigators has not been confirmed [8,68]. This rate is still far less than that (30%) after natural infection, however, as reported by the same group of researchers [68]. Permanent disability and joint destruction have also been reported, but only rarely [65,68].

Most published data indicate that these and other adverse events associated with rubella vaccine occur only in susceptible vaccinated persons [5,8]. There is no conclusive evidence that there is an increased risk of reactions in persons who are already immune at the time of vaccination [8,68,127]. Vaccination programs of adults have not led to significant rates of absenteeism or disruption in everyday, work-related activities [8,282,284–287].

Although some vaccinated persons intermittently shed virus in low titers from the pharynx 7 to 28 days after vaccination, there is no evidence that vaccine virus is spread to susceptible contacts [5,482]. Vaccine virus can be recovered from breast milk, however, and may be transmitted to the breast-fed neonate [65,353,605,606]. The vaccine virus may elicit an immune response in some exposed neonates. There is no evidence of a significant alteration in the immune response or increased risk of reactions after vaccination at a later date [66,68]. Although a mild clinical infection from transmitted vaccine virus has been reported, infection with wild-type virus might have occurred [607].

The fetotropic and teratogenic potential of rubella vaccine virus has greatly influenced vaccination practices in the United States and worldwide. With the increased emphasis on vaccinating susceptible, postpubertal women in the United States, especially recent immigrants, the need to have accurate information on the risks of the vaccine virus on the fetus became even more important.

From 1971–1988, the U.S. Centers for Disease Control and Prevention (CDC) followed to term prospectively 321 pregnant women known to be susceptible to rubella by serologic testing who were vaccinated in the period from 3 months before to 3 months after conception (see Table 28–4) [69,266]. Approximately one third received vaccine during the highest risk period for viremia and fetal defects (1 week before to 4 weeks after conception) [62,69]. Of the women, 94 received HPV-77 or Cendehill vaccines, 1 received a vaccine of unknown strain, and 226 received RA 27/3 vaccine. None of the 229 offspring (three mothers who received RA 27/3 vaccine had twins) had malformations consistent with congenital rubella infection.

Although the observed risk of congenital defects is zero, from the obtained data in the United Kingdom, United States, Germany, and Sweden, a small theoretical risk of 0.5% (upper bound of 95% confidence limit 0.05%) cannot be ruled out. Limiting the analysis to the 293 infants born to susceptible mothers vaccinated 1 to 2 weeks before to 4 to 6 weeks after conception, the maximum theoretical risk is 1.3%. This risk is substantially less than the greater than 20% risk for CRS associated with maternal infection during the first 20 weeks of pregnancy and is no greater than the 2% to 3% rate of major birth defects in the absence of exposure to rubella vaccine [69,109,556].

These favorable data are consistent with the experience reported with Cendehill and RA 27/3 vaccines in the Federal Republic of Germany and the United Kingdom [64,67]. None of 98 infants in the Federal Republic of Germany and none of 21 infants in Great Britain whose mothers were known to be susceptible when vaccinated were born with congenital anomalies consistent with CRS. The most reassuring information comes from a rubella vaccine mass campaign involving 16 million women in Brazil during 2001–2002, among whom were 2327 susceptible, pregnant women. Follow-up studies on 76% of these women revealed an infection rate of 3.6% among their newborns, but no evidence of increased abortion, stillbirth, preterm birth, or CRS [608,609]. Similar negative data were reported from Costa Rica [610].

Although fetal infection occurs, if rubella vaccine has any teratogenic potential, it must be rare.

### Vaccination Recommendations

The control of rubella and congenital rubella in the United States has been predicated on universal immunization of children, with a single dose of vaccine given after the first birthday, and selective immunization of postpubertal and susceptible postpartum women. This approach remains the basis for current recommendations of the Advisory Committee on Immunization Practices (ACIP) of the Public Health Service and the American Academy of Pediatrics (AAP) [266,268]. Part of this success in control of rubella and congenital rubella has come from the recommended use of rubella vaccine as a component of the combined MMR vaccine, which in the United States is given routinely to 15-month-old children. As concerns arose about measles in adolescents and adults, attributed to the existence of a cohort of young adults representing the 2% to 10% failure rate for a single dose of measles vaccine and the theoretical possibility of waning immunity after successful immunization in early childhood, the ACIP and AAP added a second dose to the measles immunization schedule in 1989. The specific recommendation was that the second dose be given just before school entry or in the prepubertal period and that the vaccine be given as the MMR vaccine [266,268].

Rubella immunization (as MMR vaccine) should be offered to all women of childbearing age who do not have acceptable evidence of rubella immunity. Given the current data, routine screening of postpuberal women for susceptibility before rubella vaccination is no longer recommended. Women should understand the theoretical risk of fetal infection, however, and be advised not to become pregnant for at least 28 days after vaccination [276]. Known pregnancy is still considered a contraindication.

Missed opportunities should not be confused with bona fide contraindications for rubella immunization. These include the following:

1. Severe febrile illness
2. Altered immunity from congenital immunodeficiency; from acquired diseases such as leukemia, lymphoma, and generalized malignancy; and from therapy with radiation, corticosteroids, alkylating drugs, and antimetabolites
3. History of an anaphylactic reaction to neomycin (the vaccine does not contain penicillin)
4. Pregnancy, albeit because of theoretical concerns

Because vaccine virus is not transmitted through the nasopharynx, the presence of a susceptible pregnant woman in a household is not a contraindication for vaccination of other household members. Vaccine virus is present in breast milk and can infect the neonate, but breast-feeding also is not a contraindication to vaccination. Although vaccination is usually deferred for 8 to 12 weeks after receipt of immunoglobulin, receipt of anti-Rho (D) immunoglobulin (human) or blood products does not generally interfere with seroconversion and is not a contraindication to postpartum vaccination [611–614]. In this situation, 6- to 8-week postvaccination serologic testing should be performed, however, to ensure that seroconversion has occurred [613]. This is the only situation in which postvaccination testing is recommended as routine.

## OUTBREAK CONTROL

Although outbreak control is an after-the-fact method of prevention, rapid, aggressive responses to outbreaks are necessary to limit the spread of infection and can serve as a catalyst to increase immunization levels. Although there is no conclusive evidence that vaccination after exposure prevents rubella, there are also no data to suggest that vaccinating an individual incubating rubella is harmful. Vaccination programs initiated in the middle of an outbreak serve to protect persons not adequately exposed in the current outbreak from future exposures.

Although laboratory confirmation of cases is important, control measures—including isolation of suspected cases or susceptible exposed persons, vaccination or exclusion of susceptible persons, and confirmation of the immune status of exposed pregnant women—should be implemented as soon as a suspected case has been identified (see "Management Issues"). Ideally, mandatory exclusion and vaccination of susceptible individuals should be practiced to ensure high rates of vaccination in the shortest possible period, particularly in the medical setting. Vaccination during an outbreak has not been associated with significant absenteeism in the workplace [8,282,284–287]. Vaccination before the occurrence of an outbreak is preferable, however, because vaccination causes far less disruption of routine work activities and schedules than rubella infection.

## SURVEILLANCE

Surveillance of rubella and CRS is necessary for rubella prevention because the information can be used to evaluate the progress of the immunization program; to identify high-risk groups that would benefit from specific interventions; and to monitor the safety, efficacy, and durability of the vaccine. Surveillance can also draw attention to small numbers of cases before they develop into sizable outbreaks. Because rubella and CRS are reportable diseases, all suspected cases should be reported to local health officials.

## STRATEGIES FOR ELIMINATION OF RUBELLA AND CONGENITAL RUBELLA SYNDROME

Elimination of rubella and CRS has been achieved in many countries (e.g., U.S., Sweden, Finland, Cuba), and two World Health Organization (WHO) regions have established elimination goals. As part of the strategy, integration with the measles elimination goal is critical. For all strategies for elimination, universal childhood vaccination is key with maintenance of high coverage. Although various elimination strategies have been used, the strategy that PAHO has recommended includes introduction of rubella-containing vaccines into routine vaccination programs for children 12 months of age and conducting a one-time mass campaign in adolescents and adults and

periodic follow-up campaigns in children younger than 5 years. In the PAHO experience, it is necessary to vaccinate both males and females [25].

Given the frequency of international travel, all countries will remain at risk of imported disease during the foreseeable future. Maintaining high levels of immunization, ongoing surveillance (recognizing that the sporadic nature of new cases likely will add to delay in diagnosis), and prompt outbreak control measures remain critical for achieving and maintaining elimination of rubella. The efforts under way in the Western Hemisphere can be a global model that eventually will make rubella and CRS matters of historic interest [615].
